

RADIOLOGY

A MONTHLY JOURNAL DEVOTED TO CLINICAL RADIOLOGY AND ALLIED SCIENCES

Owned and Published by
THE RADIOLOGICAL SOCIETY
OF NORTH AMERICA
As its Official Journal

JUNE, 1932

Volume XVIII

Number 6

Distributed by 49 Victor Supply Depots

“DETAIL”

The Phenomenal growth of Agfa Film popularity since 1927 is due to distinct advantages in clearness—contrast and density. With Agfa Film you can bring out those finer detail shadows that mean so much in the critical diagnosis of soft tissue areas.

Entered at the post office at Saint Paul, Minnesota as mail matter of the second class at the special rate of postage provided for in Sec. 1103 Act of October 3, 1917 authorized July 1, 1918

RADIOLOGY

A MONTHLY JOURNAL DEVOTED TO CLINICAL RADIOLOGY AND ALLIED SCIENCES

CONTENTS FOR JANUARY, 1932

GROUP OF PAPERS BY MEMBERS OF THE STAFF OF GRACE HOSPITAL, DETROIT

| | | |
|---|--|-----|
| LUNG ABSCESS | <i>William A Hudson, M D, M Sc, F A C S, Detroit, Michigan</i> | 1 |
| THE ROENTGEN RAY IN DIAGNOSIS AND PROGNOSIS OF UPPER URINARY TRACT INFECTION | <i>H W Plaggemeyer, M D, and C G Welt- man, M D, Detroit, Michigan</i> | 23 |
| FRACTURES AND INCOMPLETE DISLOCATIONS OF THE MANDIBLE OR MAXILLA | <i>Lloyd Rogers, D D S, C Taylor Hall, D D S, and John H Shackelford, D D S, Detroit, Michigan</i> | 28 |
| INTRAVENOUS UROGRAPHY | <i>Robert E Cumming, M D, Detroit, Mich- igan</i> | 41 |
| THE DEMONSTRATION AND SIGNIFICANCE OF NEPHROPTOSIS AND URINARY STASIS | <i>Harold L Morris, M D, F A C S, De- troit, Michigan</i> | 56 |
| EAR COMPLICATIONS IN ACUTE CRANIOCER- BRAL INJURIES A STUDY OF 476 CASES | <i>E S Gurdjian, M D, Ph D, Detroit, Michigan</i> | 74 |
| GASTRIC TUMORS. | <i>Maurice F Dwyer, M D, Seattle, Wash- ington</i> | 80 |
| DIVERTICULOSIS OF THE COLON | <i>Franz M Groedel, M D, Bad-Nauheim, Germany</i> | 88 |
| TUMORS OF THE MALE BREAST, BASED ON A STUDY OF 31 CASES | <i>Bernard F Schreiner, M D, F A C S, Buffalo, New York</i> | 90 |
| THE CONCEPT OF DOSAGE AND THE DEFINI- TION OF THE r-UNIT (ROENTGEN UNIT) | <i>Dr Richard Glocker, Stuttgart, Germany</i> | 93 |
| INTERNATIONAL COMPARISON OF X-RAY STANDARDS | <i>Lauriston S Taylor, Washington, D C</i> | 99 |
| MEDICO-LEGAL DEPARTMENT | | 115 |
| CASE REPORTS AND NEW DEVICES | | |
| A CASE OF PULMONARY FIBROSIS OF OB- SCURE ETIOLOGY, WITH BILATERAL SPON- TANEOUS PNEUMOTHORAX | <i>Major Albert Bowen, M C, U S A, Honolulu, T H</i> | 121 |
| THE RADIOGRAPHIC DETECTION OF THE CATFISH SPUR AS A FOREIGN BODY | <i>Robert B Taft, M D, B S, Charleston, S C</i> | 123 |
| LYMPHOBLASTOMA AND TEMPERATURE IN IRRADIATED PATIENTS | <i>James R Gemmill, M D, Monessen, Penna</i> | 124 |

Distributed by 49 Victor Supply Depots

Victor "KX" Valve-Tube X-Ray Apparatus covers entire field of roentgenology

WHATSOEVER the requirements are for x-ray energy sufficient to produce the finest diagnostic chest radiographs in 1/30th to 1/120th of a second, or for x-ray therapy with 30 mri at 200 kv p., or 10 mri at 400 kv p., the Victor "KX" series offers the selection of a unit with which

KX-1 Installation, St Paul's Hospital,
Vancouver, B.C.

THE "KX" SERIES

| Model | Radiography | Fluorescopy and Therapy |
|-------|----------------------------|---------------------------|
| KX-1 | 1000 Ma at 85 Kv.P. | 10 Ma at 125 Kv.P. |
| KX-2 | 500 Ma at 85 Kv.P. | 10 Ma. at 140 Kv.P. |
| KX-3 | 100 Ma. at 100 Kv.P. | 30 Ma. at 200 Kv.P. |
| KX-4 | 100 Ma. at 100 Kv.P. | 10 Ma. at 125 Kv.P. |
| KX-C1 | | 10 Ma. at 400 Kv.P. |

the given range of diagnostic and therapeutic service is obtained under ideal conditions

It may be said, unequivocally, that never before in the x-ray art has diagnostic apparatus been available with which the x-ray energy was under the control of the operator to the degree now realized in the "KX" series. When we speak of obtaining, as a routine procedure, radiographs of preferred contrast and density, using energies as high as 1000 mri at 85 kv p., with exposures as fast as 1/120th second, it gives a very definite idea of what is now being realized by users of the KX-1 Unit, for instance.

Only a well balanced engineering design, comprising integral parts of highest efficiency, can bring about the unprecedented results now realized with "KX" apparatus.

The "KX" series merits your investigation. Descriptive literature on request.

ANNOUNCING

A New Series "XP" Coolidge X-Ray Tubes

HERE are the outstanding features of the new "XP" series of eight diagnostic Coolidge tubes, the result of extensive research and engineering work.

The "XP" series is representative of all that the science of physics has thus far contributed to the knowledge of x-ray phenomena together with the skill in design and manufacture that follows many years of experience in the production of the world famous Coolidge tube.

By using a 20° anode with an elongated focal spot it is introduced by Benson* in 1916, a smaller projected focus has been made possible thereby offering a choice of increased film detail or greater speed of radiography.

The x-ray protective cover is entirely independent of the vacuum unit or tube proper, thus simplifying construction and increasing the reliability of the latter. Furthermore, economy and convenience are realized when replacement of the tube (vacuum unit only) becomes necessary.

Three different focal spot sizes are available, also a double focus with either air cooled or water cooled radiator. An air cooled model may be converted to water cooled, or vice versa by simply unscrewing one radiator and substituting the other.

| |
|---|
| X Ray Protection |
| Smaller Focal Spots |
| Higher Energy Ratings |
| Replacement Economy |
| Air and Water-Cooled Radiators Interchangeable |
| Extraordinary Freedom from Risk of Puncture |
| Utmost Reliability Due to Practical Design of Vacuum Unit |

*U. S. Patent No. 1,174,041 granted March 7, 1916. Assigned to General Electric X-Ray Corporation in October 1931.

Above: "XP" Coolidge Tube enclosed in protective cover with water cooled radiator.
Right: Air Cooled Radiator which is interchangeable with above water cooled radiator.
Below: The Coolidge Tube as it appears when supplied as a replacement unit.

Thus the Coolidge tube, the advent of which marked a new era in x-ray science, points to new achievements and higher standards for the immediate future of the art.

LUNG ABSCESS¹

By WILLIAM A. HUDSON, M.D., M.Sc., F.A.C.S., Grace Hospital, DETROIT, MICHIGAN

THE thoracic surgeon, like any other physician who carries on a special type of medical practice, finds that he must have the constant co-operation and support of men occupied with other fields in medicine. The roentgenologist is one upon whom the thoracic surgeon must make frequent demands. The help obtained is more satisfactory if the contact is close and the exchange of ideas is free. Many difficult questions can in this way be solved that would otherwise be forced to await future development for their solution.

Because of our constant association with roentgenologists it is felt that it might be of advantage to record some of our experiences. We will try to point out some of the conditions we have encountered which have proven of value to us in arriving at our conclusion as early as possible.

DEFINITION

By lung abscess, we mean a destructive process in the lung tissue originating within the lung itself as a result of an invasion of the lung by pyogenic micro-organisms. All suppurative processes of the pleural cavity, such as empyema, whether general or

local, and all tuberculous cavities are excluded.

ETIOLOGY

The one etiologic factor common to all lung abscesses is the propagation of pyogenic micro-organisms and their introduction into the lung substance. Any pus-forming micro-organisms, then, may be the etiologic or causative factor. All produce radiological evidence of much the same character. We have noted that lung abscesses produced by certain micro-organisms present some features in a more striking manner than others, for instance, abscesses caused by fuso-spirochetal organisms of Vincent are prone to spread rapidly without regard to fascial planes or lobar boundaries (Case I) and are associated with a foul odor, while abscesses caused by *B. Friedlander* may spread less rapidly—they seem to excavate the lung.

While all lung abscesses present radiological evidence of much the same character, there is, however, such a wide range of findings at different stages in the development of lung abscesses that it is not surprising that difficulty is at times encountered in the diagnosis of such processes. A considerable proportion of the lung abscesses encountered is found to follow some known condition. In certain types of abscesses, i.e., post-ton-

THE thoracic surgeon, like any other physician who carries on a special type of medical practice, finds that he must have the constant co-operation and support of men occupied with other fields in medicine. The roentgenologist is one upon whom the thoracic surgeon must make frequent demands. The help obtained is more satisfactory if the contact is close and the exchange of ideas is free. Many difficult questions can in this way be solved that would otherwise be forced to await future development for their solution.

Because of our constant association with roentgenologists it is felt that it might be of advantage to record some of our experiences. We will try to point out some of the conditions we have encountered which have proven of value to us in arriving at our conclusion as early as possible.

DEFINITION

By lung abscess, we mean a destructive process in the lung tissue originating within the lung itself as a result of an invasion of the lung by pyogenic micro-organisms. All suppurative processes of the pleural cavity, such as empyema, whether general or

local, and all tuberculous cavities are excluded.

ETIOLOGY

The one etiologic factor common to all lung abscesses is the propagation of pyogenic micro-organisms and their introduction into the lung substance. Any pus-forming micro-organisms, then, may be the etiologic or causative factor. All produce radiological evidence of much the same character. We have noted that lung abscesses produced by certain micro-organisms present some features in a more striking manner than others, for instance, abscesses caused by fuso-spirochetal organisms of Vincent are prone to spread rapidly without regard to fascial planes or lobar boundaries (Case I) and are associated with a foul odor, while abscesses caused by *B. Friedlander* may spread less rapidly—they seem to excavate the lung.

While all lung abscesses present radiological evidence of much the same character, there is, however, such a wide range of findings at different stages in the development of lung abscesses that it is not surprising that difficulty is at times encountered in the diagnosis of such processes. A considerable proportion of the lung abscesses encountered is found to follow some known condition. In certain types of abscesses, *i.e.*, post-ton-

¹In this issue will be found a group of papers by members of the Staff of Grace Hospital Detroit

silectomie, it is possible to definitely establish the date of the onset. Should one follow such a complication through all of its phases one would be able to obtain certain evidence of value.

ROENTGEN EVIDENCE

At the onset of a lung abscess, the formation of which is due to aspiration, infection, and blockage of secretion, the first roentgenographic evidence of abscess formation is the appearance of an area of increased density in the region of the bronchial obstruction. This area of increased density is confined at first to that portion of the lung immediately adjacent to the obstruction and along the bronchial tree distal to the obstruction. The markings of the bronchi distal to the obstruction most frequently appear as radiating lines extending into the periphery of the lung field (Cases II and III). Succeeding studies show extension of the area of increased density until, in time, an entire lobe or more may be involved in the process (Case IV). The speed with which the lesion extends depends upon the virulence of the infecting organisms and upon the interference with endobronchial drainage. As the density of the involved portions of the lung increases, the usual lung markings become obliterated, even the peribronchial radiations being lost in a shadow of uniform density (Case IV). Later, areas of decreased density may appear in this shadow of uniform density. These may be circular or irregular in outline, they may be single or multiple. It may also be noted that at the most dependent portion of these areas of decreased density the outline is horizontal, resembling a fluid level. Such areas can usually be interpreted as areas of destruction or cavitation, and in cases in which a horizontal line represents the most dependent portion of the rarefied area one is usually safe in interpreting such a finding as a fluid level (Cases V and VI).

Abscess cavities are rarely surrounded by recognizable capsules, but appear, rather, as defects within boundaries of uniform density which surround them (Case VI). Cavities which have attained a moderate size practically always communicate with a bronchus. The free access of air causes their fluid contents to assume a horizontal level, which is surmounted by a hemispherical air space. Such a horizontal level, which can be caused to shift by a change of position, is so characteristic of an accumulation of fluid with air superimposed that it constitutes positive evidence of a cavity even when, as frequently happens, the walls of the latter are indistinct or invisible. Cavities vary in size from some which are barely distinguishable (Case VIII, Fig. 2) to others which occupy a whole lobe (Case VI). This entire picture, from the very slightest increase in density of the pulmonary shadows to the changes indicative of cavity formation with fluid, may be seen to develop during a matter of from one to two weeks.

At times the roentgenologist must vary his procedure in order to detect cavities which are located in unusual situations. In Case VII is illustrated an irregular cavity which lies within a diseased right lower lobe. It was necessary to resort to the oblique position in order to disclose this cavity at its best, as it was partially obscured by the heart in the dorsoventral position. The same difficulty was encountered to a lesser degree in another case of lower lobe abscess on the right side. Here again, the cavity was partly hidden by the right ventricle in such a way that the evidence of its presence was not detected and doubt arose as to the nature of the patient's illness (Case XII).

LOCATION OF THE ABSCESS

The exact localization of the abscess, which we owe in such full measure to the roentgen examination, has a practical bearing which transcends its value as a mere

method of diagnosis To the surgeon who contemplates the drainage of a cavity or the incision of a lobe, or to the endoscopist, the situation of the abscess will determine his method of approach, and for this purpose an accurate localization is essential Even with the roentgen examination, this is not always possible Especially on the right side, the overlapping of the three lobes in the middle third of the chest will render it difficult to assign an infiltration in this region to any one lobe or to the adjacent portions of all three lobes Here stereoscopic examination may be of service In Case VI, for example, it is impossible to deduce, from the plate alone, whether the abscess is situated in one or more lobes, at bronchoscopy it was found that drainage occurred by way of the middle and lower lobe bronchi In these cases, dependence must be placed on the location of the physical signs and bronchoscopic findings to distinguish between an affection of the lower part of the upper lobe and upper part of the lower lobe, the shadows of which will be superimposed on the plate The findings at endoscopic examination are most dependable The endoscopist is able to identify the bronchus from which the drainage takes place, thereby determining the portion of the lung involved, unless the process has involved one lobe of lung and ruptured through an interlobar fissure to establish drainage through the bronchus of an adjacent lobe Some would hesitate to make a diagnosis of lung abscess during that stage when the first area of increased density appears (Cases II and III), preferring to await the time when an area of destruction has developed and a definite fluid level has presented itself, as in Case VI

Experience has shown us that a fluid level may not reveal itself when frank abscess formation has taken place Frequently, cavities which are full of secretion, especially when they are small, may be entirely obscured by the increased density of the lung about them (Case VIII) Then, too, lique-

faction can take place without the presence of sufficient gas or air to denote a fluid line The presence of a fluid level in an area of increased density in a lung field usually indicates the presence of a communication between the space containing the fluid and the tracheobronchial tree We have seen cases which failed to show such a fluid level, present a fluid level immediately after the institution of endobronchial drainage (Case IX) Certainly the abscess was present previous to the drainage and the diagnosis would have been of greater value could the development of the cavity have been anticipated and the diagnosis of an impending abscess have been made We are cognizant of the fact that the roentgenologist would require certain clinical information before making such a diagnosis, but we know of no reason why he should not be permitted to profit by all available information in the hands of the clinician in arriving at a conclusion

It is obvious that the radiologist will be aided materially in his diagnosis of impending abscess if he makes frequent roentgen-ray examinations, even daily, during the period of study It is not sufficient, however, to merely make X-ray plates and send the patient back to his room—a fluoroscopic study should also be made Frequently one finds that areas of altered lung markings can be brought out more satisfactorily in the X-ray plates, if at first the proper angle is selected during a fluoroscopic examination In addition, the mobility of the various contents of the thoracic cage can best be studied by fluoroscopy

DIFFERENTIAL DIAGNOSIS

Lobar Pneumonia—In the acute stage of a developing lung abscess the consolidation may develop in the hilum region, as in lobar pneumonia A second plate at the end of twenty-four hours or even a third after forty-eight hours should serve to differen-

sillectomie it is possible to definitely establish the date of the onset. Should one follow such a complication through all of its phases one would be able to obtain certain evidence of value.

ROENTGEN EVIDENCE

At the onset of a lung abscess, the formation of which is due to aspiration infection and blocking of secretion, the first roentgenographic evidence of abscess formation is the appearance of an area of increased density in the region of the bronchial obstruction. This area of increased density is confined at first to that portion of the lung immediately adjacent to the obstruction and along the bronchial tree distal to the obstruction. The markings of the bronchi distal to the obstruction most frequently appear as radiating lines extending into the periphery of the lung field (Cases II and III). Succeeding studies show extension of the area of increased density until, in time, an entire lobe or more may be involved in the process (Case IV). The speed with which the lesion extends depends upon the virulence of the infecting organisms and upon the interference with endobronchial drainage. As the density of the involved portions of the lung increases, the usual lung markings become obliterated, even the peri-bronchial radiations being lost in a shadow of uniform density (Case IV). Later, areas of decreased density may appear in this shadow of uniform density. These may be circular or irregular in outline, they may be single or multiple. It may also be noted that at the most dependent portion of these areas of decreased density the outline is horizontal, resembling a fluid level. Such areas can usually be interpreted as areas of destruction or cavitation, and in cases in which a horizontal line represents the most dependent portion of the rarefied area one is usually safe in interpreting such a finding as a fluid level (Cases V and VI).

Abscess cavities are rarely surrounded by recognizable capsules but appear, rather, as defects within boundaries of uniform density which surround them (Case VI). Cavities which have attained a moderate size practically always communicate with a bronchus. The free access of air causes their fluid contents to assume a horizontal level, which is surmounted by a hemispherical air space. Such a horizontal level which can be caused to shift by a change of position, is so characteristic of an accumulation of fluid with or superimposed that it constitutes positive evidence of a cavity, even when, as frequently happens, the walls of the latter are indistinct or invisible. Cavities vary in size from some which are barely distinguishable (Case VIII, Fig. 2) to others which occupy a whole lobe (Case VI). This entire picture from the very slightest increase in density of the pulmonary shadows to the changes indicative of cavity formation with fluid may be seen to develop during a matter of from one to two weeks.

At times the roentgenologist must vary his procedure in order to detect cavities which are located in unusual situations. In Case VII is illustrated an irregular cavity which lies within a diseased right lower lobe. It was necessary to resort to the oblique position in order to disclose this cavity at its best as it was partially obscured by the heart in the dorsoventral position. The same difficulty was encountered to a lesser degree in another case of lower lobe abscess on the right side. Here again the cavity was partly hidden by the right ventricle in such a way that the evidence of its presence was not detected and doubt arose as to the nature of the patient's illness (Case XII).

LOCATION OF THE ABSCESS

The exact localization of the abscess, which we owe in such full measure to the roentgen examination, has a practical bearing which transcends its value as a mere

for comparison of the condition at varying stages in the healing process. Only too often it happens that the physical signs may entirely disappear, temperature and sputum may disappear, and the patient may feel so well that a remaining focus will not be suspected. Roentgenographic studies may disclose a focus, and, so long as such a focus remains, it is a potential source of danger for further inoculation and spread of the disease. Cases VI, XVII, and XVIII illustrate instances which have been followed with X-ray studies. All these patients are now well.

We have always maintained that the one principle which must be strictly adhered to in the treatment of lung abscess regardless of the method used to obtain drainage, is that of efficient drainage. Needless to say, the more conservative the measures used the more desirable they become, provided the method is efficient. Physical signs and clinical observations serve to give some indication as to the efficiency of the drainage established, but it remains for roentgenographic examinations to pronounce the final word as to the efficiency of the method used and as to the desirability of discontinuing treatment. The roentgen studies enable one to correct defects in the posture selected for postural drainage. Bronchoscopic dilatations and aspirations can be carried out more efficiently if frequent roentgen studies are made to determine the rate of disappearance of the fluid level and pneumonitis and the closure of abscess cavities.

While it is true that a certain percentage of lung abscesses will heal without treatment other than postural drainage, it is too often the case that an abscess is permitted to go without other treatment until its walls have become indurated and much time has been lost. Many such abscesses require open surgical drainage (Cases XVIII and XIX), with its accompanying high rates of mortality and deformity. We have noted however, that a much smaller number of lung

abscesses require open drainage when they are followed closely by roentgen-ray studies at the same time that postural drainage and bronchoscopic drainage are being used. In fact, by combining posture and bronchoscopic drainage with careful roentgen-ray studies a very large percentage of lung abscesses can be cured without resorting to more radical measures. In making these suggestions we are not overlooking the fact that approximately 50 per cent of acute lung abscesses heal without any form of treatment. We feel, however, that the important thing is for us to strive to raise our percentage of healed abscesses from 50 per cent to as near 100 per cent as possible, without the aid of radical measures, if possible, and endoscopy in our experience has proven to be the most valuable aid at our command. We are better enabled to avoid the chronic lung abscesses which require months to heal by applying endoscopic methods of drainage as soon as we are able to make a diagnosis of impending lung abscess.

We realize that in many quarters the roentgenologist is expected to merely make a diagnosis from his X-ray films, in many instances without the aid of clinical evidence. From a considerable experience in the treatment of suppurative lesions of the lung, we have arrived at the point where we expect our roentgenologist not only to make a diagnosis, but we feel that he must go further, inasmuch as in many instances he will see the case earlier than the thoracic surgeon—we feel that he should make suggestions as to the probable necessity of intervention. He should call to the attention of the referring physician such findings as suggest the need of endoscopy early, so as to enable the patient to avoid the more severe complications and the more drastic measures that might be required at a later date.

The medical treatment of acute pulmonary suppuration is expectant and in reality no specific drug can be recommended. In the

trite the lesion mustache the consolidation in lobar pneumonia is usually much more rapid in its development than in the lung abscess.

Messier's Localized Pneumonia - The differentiation of an acute lung abscess from a massive pneumonia or a localized pneumonitis may be somewhat difficult. However, in the classical picture of massive, telestasic the characteristic findings (Case X) of a narrow hemithorax with an increased density of the involved portion of the lung and the narrow interspace, with the displacement of the mediastinal contents i.e. heart and trachea toward the involved side, and the elevation of the diaphragm serve as differential points to contrast with those previously described in the case of a lung abscess. In case of a localized pneumonitis the classical roentgen-ray findings may not all be present. If however the roentgen studies have been made shortly after the onset of the pneumonitis, there is always some evidence of fixation, elevation of the diaphragm or of contraction of the interspaces, with some displacement of the mediastinum. These findings may at times be seen at their best under the fluoroscope. It must be borne in mind that many post-operative lung abscesses develop in areas that were in the beginning merely areas of telestasis, and that relief from the bronchial obstruction in many instances prevents abscess formation.

Empyemas are also at times confused with acute lung abscesses. If however, the empyema is located adjacent to the mediastinum, there will be displacement of the mediastinal contents toward the good side (Cases XI and XII), in contrast to no displacement of these structures as in lung abscess. If the abscess is located in the peripheral portion of the lung or there is an intra-lobar empyema on the right especially the free use of the fluoroscope with the patient turned so as to bring the diseased area into view from all angles will be of aid. It may not be possible to make a fixed differential

diagnosis by means of the X-ray alone (Case XIII).

Chronic lung abscess cannot be entirely differentiated from chronic tuberculosis with cavity, by X-ray examination alone (Compare Case VII and Case XIV.)

A carcinoma of the lung may become secondarily infected and an acute abscess may develop in spite of having been made previous to the development of the abscess. Comparison may render the differential diagnosis much easier.

A chronic lung abscess can be differentiated from chronic bronchiectasia by X-ray studies such studies being rendered more valuable by the use of lipiodol as a contrast medium. In certain instances a lung abscess which fails to be revealed by the ordinary plates can best be shown by the use of lipiodol injected through a bronchoscope (See Cases VII and XV.)

Lung abscesses secondary to a foreign body, even those foreign bodies of metallic nature, are overlooked at times because of the failure of the physician to make use of the X-ray or because of improper roentgen-ray technic, when, on the other hand, a properly taken X-ray plate would point the way to the proper diagnosis and treatment of the case (Case XVI).

ROENTGENOLOGICAL AID IN TREATMENT

The part played by roentgenography in the treatment of lung abscess does not end with the diagnosis. Since the position and character of an abscess is a factor in determining the type of treatment to be instituted, the roentgen evidence becomes of utmost importance as a check on the efficacy of whatever line of treatment is instituted. It is a well known fact that a certain percentage of lung abscesses will heal without undue delay, following rupture of the abscess, with evacuation of its contents through a bronchus. Roentgen-ray studies are the means of making permanent records

Fig. 3 Case II

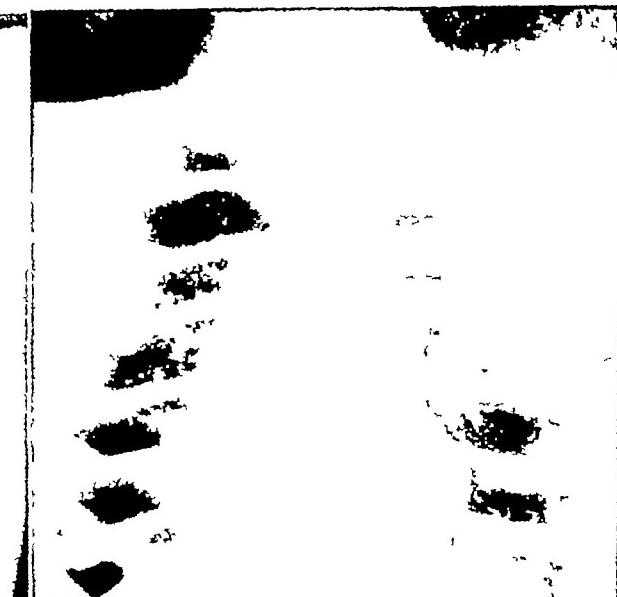

Fig. 4 Case II

CASE REPORTS

Case I—This patient was a white male about 45 years of age, who gave a history of having had all of his teeth extracted under gas anesthesia one week previous to his admission to the hospital. At that time he was very ill, and was coughing up large amounts of very foul sputum which contained many organisms, including the fusospirochetal organisms of Vincent. X-ray studies revealed extensive areas of increased density throughout the right lung field and at postmortem it was found that the right lower and middle lobes were fused across the interlobar fissure by a plastic exudate (Fig. 1), and on section (Fig. 2) it was noted that there was extensive excavation extending directly across the region of the interlobar fissure.

Case II—This patient is a white male 20 years of age, who had had some teeth extracted ten days previous to this X-ray examination (Fig. 3). Within the first week after the extraction he developed a non-productive cough and a low grade temperature, with marked malaise. The X-ray stud-

ies show an area of increased density in the medial portion of the right lower lobe, with radiating lines extending toward the periphery. The diagnosis was obstruction to a division of the right lower lobe bronchus. Bronchoscopy was done and a plug was removed from a medio-posterior division of the right lower lobe bronchus. Microscopic

Fig. 5 Case III

Fig 1 Case I

Fig 2 Case I

adoption of expectant treatment and the attempt to evacuate the cavity by way of the bronchi without resort to more active measures, it is to be appreciated that there is the risk of extension of the suppurative process into nearby or remote parts of the lung, the development of a complicating pneumonia, empyema, cerebral abscess, or septicemia, and that in consequence of delay the local or general condition may become less rather than more favorable for the application of other methods of treatment.

It is not an everyday occurrence for the general practitioner to encounter a lung abscess and one must not censure him too severely if he does not resort to endoscopy or some conservative method of active treatment at an early date. On the other hand, the roentgenologist will see numerous cases, and if he has acquainted himself with the progress of other cases that have passed through his hands, he can with all sincerity advise intervention or at least consultation as to the advisability of intervening.

The fact that some cavities heal spontaneously is not sufficient to warrant any man

following a program of watchful waiting. The calamities will so far outweigh the successes that one can no more find justification for such delay than one could find justification for such a course in the average case of acute appendicitis.

One might summarize these experiences in the following manner:

(1) The roentgenologist is an important and necessary link in the personnel handling lung abscesses; he should make use of all clinical information available in arriving at his diagnosis.

(2) The roentgenologist should do more than arrive at a diagnosis; he should make suggestions in regard to probable need of treatment.

(3) The roentgenologist should follow his cases to learn the ultimate results.

(4) It is desirable to make a diagnosis of impending lung abscess rather than to wait for a full-blown abscess to develop before making a diagnosis.

(5) In our experience, conservative active methods of treating lung abscess have been the most satisfactory.

Fig 9 Case V

Fig 10 Case V

ray studies (Fig 7) reveal an area of markedly increased density in the region of the right middle lobe and the lower portion of the upper lobe. The lateral view (Fig 8) reveals a similar density in the region of the middle lobe. Open drainage was performed and an extensive lung abscess opened up which involved the lower half of the right upper, the entire right middle, and the upper part of the right lower lobe. Cultures revealed a staphylococcus. The patient, now at the end of six years, remains in good health.

Case V—This patient is a white female 24 years of age, with a history of a tonsillectomy under ether anesthesia two weeks before the present examination. Following the tonsillectomy she developed a cough, non-productive at first, but becoming productive of foul sputum and accompanied by temperature, loss of appetite, together with general malaise. There was severe pain over the right lower chest posterolaterally. X-ray

examination (Fig 9) reveals an area of increased density in the lower medial portion of the right lower lobe, together with a punched-out area of decreased density which has a straight line for its most dependent border. It is to be noted that there is no definite wall or capsule about this area of decreased density, which simply occurs in the middle of an area of otherwise equal density. Attention should be directed, also, to the deformity of the spine. Diagnosis of lung abscess was made. Bronchoscopic aspirations were done and in the follow-up plate (Fig 10) it is to be noted that the area of increased density, at the right base, has entirely disappeared and that there no longer remains any evidence of the punched-out area seen in the first studies. Instead, there appear, now, normal lung markings. Meanwhile the patient's physical signs, temperature and cough, have entirely disappeared.

It is to be noted that the clinical course in the case of this patient was prolonged over

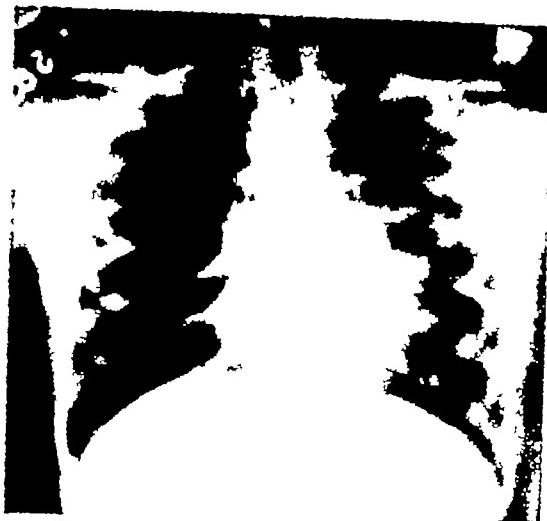

Fig. 6—Case III.

cough. It was noted that in the X-ray film there was seen an area of increased density in the medial portion of the right lower lobe, adjacent to and confluent with the heart shadow. Temperature at this time was 105°

Fig. 8—Case IV.

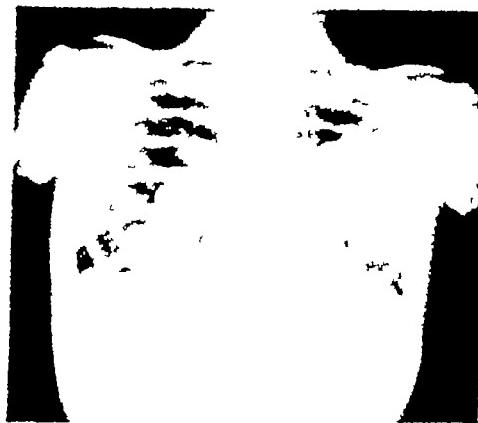

Fig. 7—Case IV.

examination proved this to be a piece of peridental membrane. Cultures revealed virulent long chain streptococcus. A second film, made within forty-eight hours after bronchoscopic removal of the plug, reveals a disappearing shadow (Fig. 4). At the same time the patient's temperature and cough have entirely subsided.

Case III.—This patient is a white female 8 years of age who entered the hospital with a history of tonsillectomy under ether anesthesia eight days previously and five days previous to X-ray examination (Fig. 5). Following the tonsillectomy there developed malaise, temperature and a non-productive

A diagnosis of an impending lung abscess due to bronchial plug was made. Bronchoscopy was done. A plug of mucus and old blood was removed from the right lower lobe bronchus. A virulent short chain streptococcus was obtained on culture. Immediately, the condition improved, the temperature reached normal within twelve hours, and did not rise again above 99° . The X-ray film (Fig. 6) at the end of twenty-four hours reveals a clearing of the area of increased density, with the reappearance of the right heart shadow.

Case II.—This patient is a white male 7 years of age who underwent the operation of tonsillectomy four months previous to the present illness. Ether anesthesia was used and the anesthetic was said to have been administered with difficulty. Within two weeks after the tonsillectomy the patient developed a cough (non-productive), malaise and a temperature which ranged from 99° to 103° . He lost a great deal of weight. X-

Fig 9 Case V

ray studies (Fig 7) reveal an area of markedly increased density in the region of the right middle lobe and the lower portion of the upper lobe. The lateral view (Fig 8) reveals a similar density in the region of the middle lobe. Open drainage was performed and an extensive lung abscess opened up which involved the lower half of the right upper, the entire right middle, and the upper part of the right lower lobe. Cultures revealed a staphylococcus. The patient, now at the end of six years, remains in good health.

Case V.—This patient is a white female 24 years of age, with a history of a tonsillectomy under ether anesthesia two weeks before the present examination. Following the tonsillectomy she developed a cough, non-productive at first, but becoming productive of foul sputum and accompanied by temperature, loss of appetite, together with general malaise. There was severe pain over the right lower chest posterolaterally. X-ray

examination (Fig 9) reveals an area of increased density in the lower medial portion of the right lower lobe, together with a punched-out area of decreased density which has a straight line for its most dependent border. It is to be noted that there is no definite wall or capsule about this area of decreased density, which simply occurs in the middle of an area of otherwise equal density. Attention should be directed, also, to the deformity of the spine. Diagnosis of lung abscess was made. Bronchoscopic aspirations were done and in the follow-up plate (Fig 10) it is to be noted that the area of increased density, at the right base, has entirely disappeared and that there no longer remains any evidence of the punched-out area seen in the first studies. Instead, there appear, now, normal lung markings. Meanwhile the patient's physical signs, temperature and cough, have entirely disappeared.

It is to be noted that the clinical course in the case of this patient was prolonged over

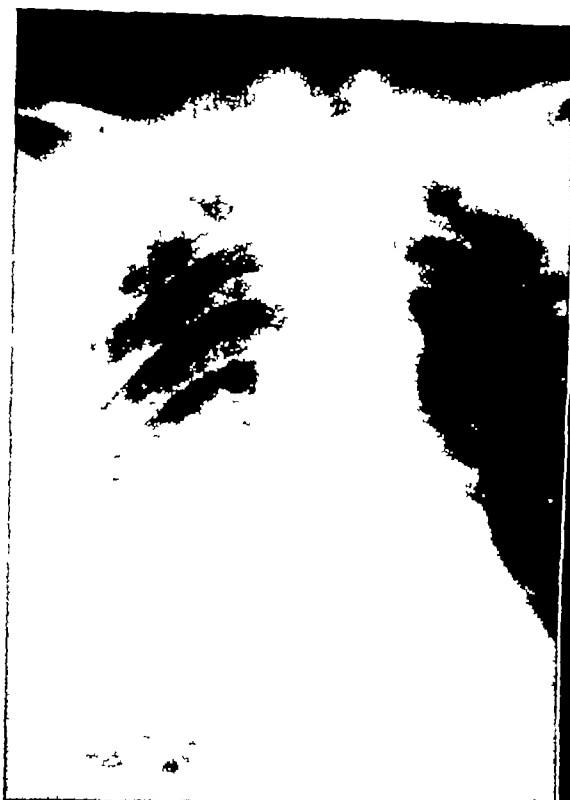

Fig 11 Case VI

Fig 12 Case VI

that of Cases II and III, the latter two requiring only one bronchoscopic drainage each, while this patient required drainages three times a week for the first three weeks in order to maintain continuous drainage.

Case VI—This patient is a white male 27 years of age. There is a history of an indefinite onset of a "flu" or grippelike character with the gradual appearance of productive cough. X-ray studies (Fig 11) reveal an area of increased density in the region of the right lower and middle lobes of the lung. There is shown in this area of otherwise uniform density an irregularly punched-out area of decreased density, and in an X-ray film (Fig 11) taken in the posteroanterior position, the patient in the upright position, there is a horizontal line at the most dependent portion of the punched-out area. With the patient lying on his left side (Fig 12) there is a shifting of this line so

that it lies parallel with the spine. With the patient in the upright position, in the lateral view (Fig 13), again an irregular punched-out area of decreased density appears, which occupies a considerable portion of the chest at this point, and the horizontal line is seen in a new position. A diagnosis of extensive lung abscess was made. Repeated bronchoscopic drainages were carried out, with entirely satisfactory results.

Figure 14 shows the scar that remains at the end of three months, as seen in a posteroanterior film, while Figure 15 shows the same in a lateral view. The enormous size of this cavity, and the prolonged and energetic treatment that was necessary, as compared with the story told by Figures 12 and 13 merely serve to emphasize the importance of an early diagnosis with early treatment in a developing suppurating lesion.

Case VII—This patient is a white male

Fig 13 Case VI

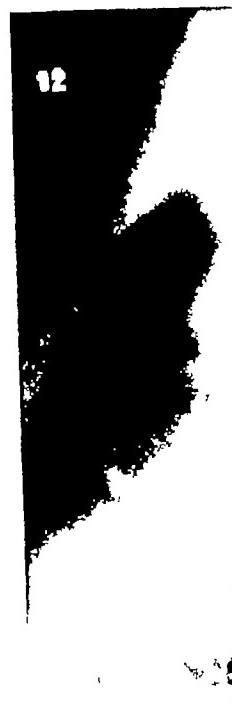

Fig 15 Case VI

Fig 14 Case VI

47 years of age, who gives a history of repeated pulmonary hemorrhages at frequent intervals over a period of twenty years. Repeated X-ray examinations have failed to reveal anything of diagnostic importance. Physical examinations revealed nothing definite in the chest. Bronchoscopy was done

and a small cavity was identified at the root of the right lung, off from the first portion of the lower lobe bronchus. This cavity was filled with lipiodol and plates made in the postero-anterior position (Fig 16) and in the oblique position (Fig 17). Diagnosis: Chronic lung abscess, right lower lobe, probably due to rupture of a suppurating lymph gland.

Case VIII—This patient is a white female about 35 years of age with a history of a cough which developed following an illness of grippelike character eight weeks previous to the present examination. Associated with the cough are malaise and a temperature up to 103° . X-ray studies in the postero-anterior position (Fig 18) reveal an area of uniformly increased density in the left upper lobe. Because of the location of this lesion pulmonary tuberculosis

was considered, but repeated sputum examinations were negative for acid-fast organisms. A diagnosis of impending lung abscess was made and bronchoscopy performed. X-ray plates taken in the same

former lesion, and the patient has remained well since.

Case IX—This patient is a white female 32 years of age who entered the hospital with a history of a cough, which developed

Fig. 16 Case VII

Fig. 17 Case VII

position (Fig. 19) following bronchoscopy show a definite decrease in the extent of the area of increased density and also reveal a punched-out area of decreased density. A third X-ray film (Fig. 20) within six weeks reveals disappearance of all evidence of the

following delivery under gas anesthesia two weeks previously. X-ray films taken in the postero-anterior position (Fig. 21) at the end of twelve days reveal an area of in-

Fig. 18 Case VIII (Damaged film)

Fig. 19 Case VIII

creased density in the lower medial portion of the right lung field. Extending off from this area of increased density are numerous fine radiating lines of similar density. A diagnosis of impending lung abscess was made. Bronchoscopy was done and an inflammatory obstruction in the right lower lobe bronchus was relieved. Cultures from the secretion revealed a streptococcus. X-ray studies (Fig. 22) now reveal an area of decreased density within the area of uniform density.

This case serves to illustrate the fact that actual destruction of lung tissue may take place without the appearance of a fluid level within the area of destruction. When drainage is established, evidence of such destruction may be had. We would repeat the importance of making, in cases in which it is possible, a diagnosis of impending lung abscess.

Case X—This patient is a white male 42 years of age who underwent an appendectomy under spinal anesthesia thirty-six hours previous to the X-ray study shown in Figure 23. Within eight hours after the operation he showed an increase in his pulse rate and within ten hours there was an increase in the temperature and respiratory

rate. Physical findings revealed a cyanotic patient with evidence of consolidation throughout the right lung field. X-ray studies revealed the characteristic findings of a massive atelectasis of the lung. Bronchos-

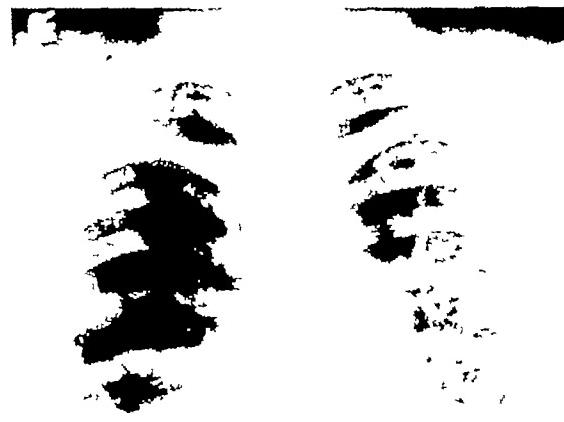

Fig. 20 Case VIII

copy was done, with immediate relief. X-ray studies taken immediately showed the clearing up of the markedly increased density in the right half of the chest, with a shifting of the heart toward its normal position.

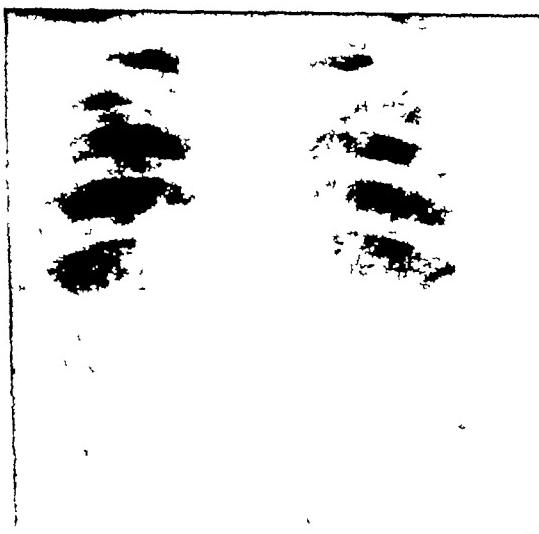

Fig. 21 Case IX.

Fig. 22 Case IX.

Fig. 23 Case X

Fig. 24 Case X

Case XI—This patient was a colored male 35 years of age, who gave a history of an illness characteristic of lobar pneumonia. After an interval of improvement there was again an increase in the symptoms, especially temperature and cough, with a small amount of sputum (without odor). X-ray studies in the postero-anterior position reveal an area of increased density

in the region of the left base near the midline, extending latterward to the chest wall with some displacement of the heart toward the right side. There is another shadow near the lateral chest wall behind the clavicle (Fig. 25). The diagnosis of lung abscess was considered in this case, but because of the displacement of the heart toward the right it was thought best to do a thoracentesis. This operation was done in the eighth interspace, about a finger's breadth lateral to the spine, resulting in the diagnosis of an encapsulated empyema. Thoracotomy gave further proof by the finding of such an encapsulation.

Case XII—This patient was a white male

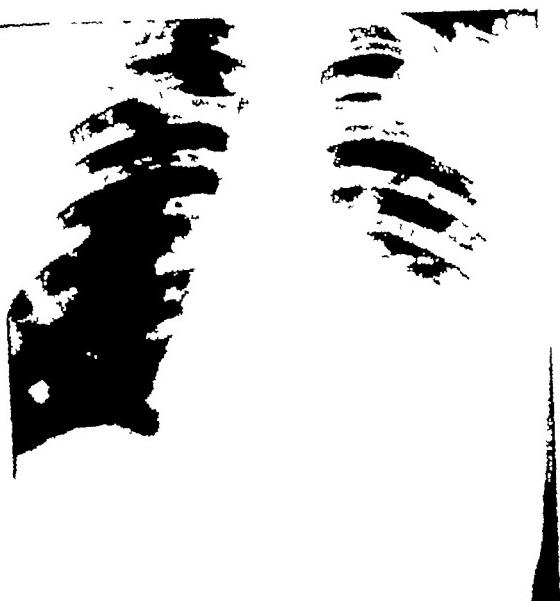

Fig 25 Case XI

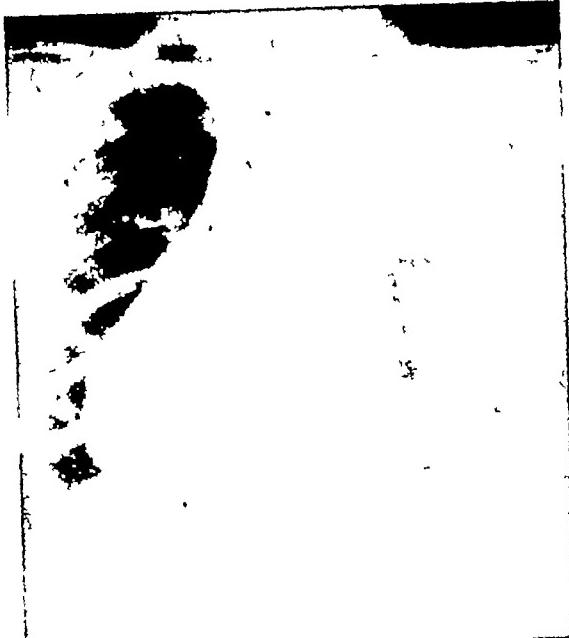

Fig 27 Case XII

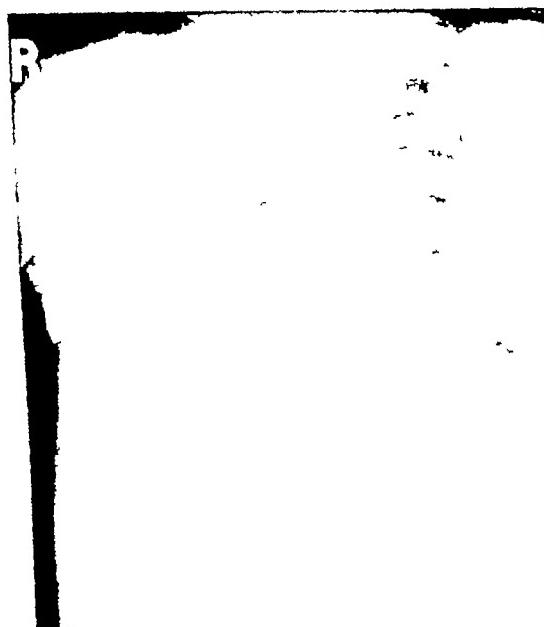

Fig 26 Case XII

Fig 28 Case XII

ray. The density is greater near the midline at the base and extends to the lateral chest wall, particularly at the level of the clavicle. As to diagnosis, a massive atelectasis following pneumonia was considered, also that of an unresolved pneumonia. However, because of the peculiar distribution of the

shadow, and the irregularity of the density in the lateral portion of the chest, a thoracentesis was done in the seventh interspace posteriorly about a finger's breadth lateral to the spine. Pus was obtained. Thoracotomy was performed, with satisfactory results. A follow-up film (Fig 27) reveals the persistence of the shadow in the upper

lung field. A thoracentesis was done through the third interspace in the axillary line and this revealed a second encapsulated empyema, which was treated by thoracotomy. The third study (Fig. 28) on this patient shows

Fig. 29 Case XIII

Fig. 31 Case XV

Fig. 30 Case XIV

Fig. 32 Case XV

the entire disappearance of the area of increased density in the right lung field following drainage of the encapsulated empyemas.

These two cases will serve to illustrate the importance of considering encapsulated empyemas in association with studies of suspected lung abscess.

Case XIII.—This patient was a white male about 18 years of age, who had a se-

vere case of diabetes. He entered the hospital with a history of an illness similar to a pneumonia, but at the end of several weeks he was expectorating large quantities of purulent material and was running a temperature. Physical examination still re-

Fig 33 Case XV

Fig 34 Case XVI

vealed a dull to flat percussion note over the right chest posteriorly. Following a first X-ray examination a thoracentesis was performed and pus obtained from the pleural space posteriorly. Thoracotomy was then performed and a second X-ray study was made (Fig 29). Note the thoracotomy tube in place. The findings that are of greatest interest, however, are as follows:

(1) An area of increased density along the right border of the mediastinum near the upper portion of which, near the level of the second rib anteriorly, one sees an area of decreased density with a horizontal line for its lower boundary.

(2) There is a second area of increased density near the level of the third rib anteriorly in the mid-clavicular line, right. The upper border of this area of increased density is also a horizontal line above which there is an irregular circular area without lung markings.

One is forced to consider the possibility of either or both of these areas representing a lung abscess. However, a thoracentesis

performed near the right border of the sternum revealed pus. A thoracotomy was then performed and it was found that the medial shadows were due to an encapsulated empyema between the right lung and the mediastinum. This had been draining by way of the interlobar fissure to the area represented by the second shadow, thence through a bronchial fistula. The single thoracotomy drained both areas. The patient made a complete recovery. The final diagnosis in this case was empyemas, encapsulated, there being three separate pockets.

Case XIV—This patient was a white male about 40 years of age who complained of a productive cough, some loss of weight, and of feeling tired. His complaints had gradually grown upon him. He did remember of having had a severe cold about four months previously. Physical examination revealed a temperature of 101° , and there was an area in the right lung field over which cavernous breath sounds were heard. X-ray study (Fig 30) revealed an area behind the third rib anteriorly on the right, which was interpreted as a cavity. The

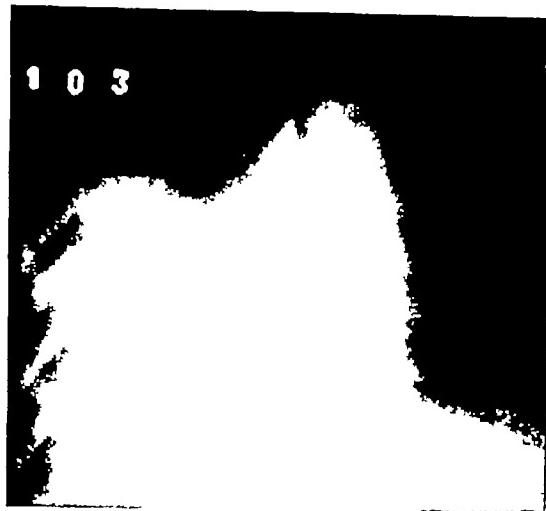

Fig. 35 Case XVI

location was such that the roentgenologist could not say whether we were dealing with an old tuberculous infection, with cavity formation, or with a non-tuberculous cavity. Sputum examination revealed tubercle bacilli. The patient was treated for tuberculosis and progressed nicely.

Fig. 36 Case XVI

Case XV—This patient was a white male 28 years of age who had been troubled with a cough ever since he could remember. He

Fig. 37 Case XVII

Fig. 38 Case XVII

expectorated a very large amount of purulent material. There were no other symptoms and his physical examination was entirely normal except for an occasional râle at the base near the midline on the right side. X-ray studies had failed repeatedly to show anything that could be interpreted as being definitely abnormal (See Figs 31 and 32). A bronchoscopy was then done and it was found that the orifice of the secondary bronchus from the lower lobe bronchus was inflamed and fixed. A tube was insinuated into the bronchus and it was aspirated, a considerable amount of purulent material being removed. Lipiodol (30 c.c.) was then allowed to flow into this area through the aspirating tube and the X-ray study was repeated (Fig 33). This revealed an area of considerable extent adjacent to and confluent with the right heart shadow which undoubtedly represented a cavity. Diagnosis Lung abscess.

This lesion was probably begun as a pleural process which ruptured through the lung to drain by way of the bronchial tree.

Case XVI—This patient was a white male 12 years of age, who gave a history of having developed a cough at the age of 4 years. He was treated at that time for whooping cough, but the cough never disappeared in spite of many previous examinations and much treatment. At the time these studies were made, the patient was very ill, with a distressful cough, purulent sputum, and a temperature of 103°. There were physical signs of a consolidation over the entire right lower half of the chest. X-ray study (Fig 34), using the regular technic for lung detail, revealed a shadow of markedly increased density over the right lower half of the chest. Inasmuch as this patient had been repeatedly examined in attempts to determine the source of his disturbance, it is felt that something more than a routine X-ray examination was necessary. Fluoroscopic studies were also made, paying particular attention to that portion of the

Fig 39 Case XVII

lung involved in the area of markedly increased density. It was noted that there was one point of density which seemed to differ from the other points of increased density. Accordingly, other X-ray studies (Figs 35 and 36) were made, using technic more suitable for bringing out bone detail. It is to be noted that there is revealed a shadow which resembles a wood screw, and that there is some irregularity in the outline of this shadow, which one might take to represent a deposit of rust or similar material about a screw. Lateral films reveal what might be threads on a screw. Bronchoscopic removal of a screw, coated with rust, resulted in the disappearance of the cough and a clearing up of the right base.

These studies are shown to emphasize the importance of fluoroscopy as well as multiple X-ray plate studies and illustrate the ease with which even a metallic foreign body may be overlooked in the lungs.

Case XVII—This patient was a white male 62 years of age who entered the hospital complaining of an illness which had

had an indefinite onset—malaise with a non-productive cough and a temperature X-ray studies at that time (Fig 37) revealed a large area of uniformly increased density occupying the middle portion of the

with postural drainage, it is to be noted that evidence of the infection has largely disappeared. The patient has remained well since Diagnosis is lung abscess of unknown etiology.

Fig. 40 Case XVIII

Fig. 41 Case XVIII

right lung field. At one point there is noted an area of decreased density, the lower border of which is a horizontal line. Diagnosis of lung abscess or pulmonary tuberculosis with cavitation was made because of these findings. However, repeated sputum examinations were negative for tubercle bacilli. A bronchoscopy was done and pus was found to be draining from the middle lobe bronchus. An aspirating tube was inserted into this bronchus and the bronchus was thoroughly aspirated. X-ray studies were again made (Fig 38) and it is to be noted that the area of markedly increased density has cleared to a considerable extent. However, the area of decreased density appears very much larger in these studies and there still remains a horizontal line. After thirty days, during which interval several bronchoscopic aspirations were carried out, along

Case XVIII.—This patient was a white male about 38 years of age who gave a history of having had a tonsillectomy performed under ether anesthesia five months previously. Two weeks following his tonsillectomy there developed a non-productive cough, marked malaise, and a temperature. During the succeeding five months he had a number of hemorrhages, coughed up large amounts of foul sputum, and lost a great deal of weight. Diagnosis of lung abscess had previously been made. He had been treated by bed rest, postural drainage, and pneumothorax. In spite of these measures the patient's condition became worse and at the time these X-ray studies (Fig 40) were made the man was extremely ill. The studies show first evidence of the previous pneumothorax at the right base. There is also an area of increased density occupying

the region of the right lower and middle lobes. Associated with this is a large area of decreased density, the lower border of which is a horizontal line. Diagnosis of lung abscess was confirmed in the absence of tubercle bacilli in the sputum. The patient was operated on and open drainage of an enormous abscess, occupying the greater portion of the lower lobe of the right lung, was obtained. Recovery was without complications, leaving a bronchial fistula. X-ray studies at the end of one year (Fig. 41) show the deformity in the bony structure as well as the amount of scar tissue that remains. Lipiodol injected through the bronchial fistula, as a means of contrasting

Fig. 42 Case XVIII

Fig. 43 Case XIX

Fig. 44 Case XIX

the bronchial tree, demonstrates the amount or the portion of the right lower lobe that remains (Fig. 42).

This case illustrates the importance of making an early diagnosis when possible. It also illustrates the degree of destruction and deformity that may be encountered.

Case XIX—This patient was a white female 8 years of age who gave a history of having had a tonsillectomy done under

ether anesthesia three weeks previously. Within the first week following the tonsillectomy there developed a non-productive cough, a temperature, and general malaise. After ten days the cough became productive, temperature remained high, and the patient's condition continued to fail. X-ray studies (Figs. 43 and 44) at the time she was seen, revealed an area of increased density occupying a considerable portion of the right

lung field. Within this area of increased density there was an area of decreased density which might be interpreted as a cavity.

Fig. 45 Case XIX

The lateral view (Fig. 44) shows the depth of this area in the antero-posterior position

Tubercle bacilli were not found in the sputum. Accordingly, diagnosis of lung abscess, post-tonsillotomie, was made. Because of its extent it was felt advisable to do an open drainage. This was accomplished by resection of ribs in the mid-axillary line, with drainage of the cavity at this point. X-ray studies at the end of six weeks show the extent to which the lesion has cleared.

This case, contrasted with the cases in which early diagnoses have been made, serves to emphasize the importance of an early diagnosis. The patient made a complete recovery.

We wish to thank all those radiologists who have been so liberal of their time and efforts when handling cases with us. We wish especially to thank Dr. Rollin H. Stevens, Dr. Hans A. Jarre, and Dr. Clyde Hasley for their unlimited patience with us.

THE ROENTGEN RAY IN DIAGNOSIS AND PROGNOSIS OF UPPER URINARY TRACT INFECTION

By H W PLAGGEMEYER, M D, and C G WELTMAN, M D, DETROIT, MICHIGAN

SINCE Nitze's epoch-making discovery of the cystoscope in 1877, no other single factor has added so much to the advance of urology or contributed so much to its scientific exactness as has the roentgen ray. Nor, by the same token, is any other branch of medicine so dependent upon the X-ray as is present-day urology. Indeed, without it, the urologist is entirely bereft of that which makes his diagnosis so positive and so nearly correct, urography and pyeloscopy having been aptly described as the urologist's most valuable aid in diagnosis.

It is an interesting chapter in the history of medicine which records the endeavors of such men as Tuffier (1897), Fenwick (1905), von Lichtenberg (1906), Keyes (1909), Uhle and Pfahler (1910), and others, in their efforts to render the upper urinary tract opaque to the roentgen ray. Many methods were used and discarded because of certain untoward effects, until, at the present time, probably the most widely used method is that of injecting sodium iodide of from 12 to 30 per cent solution until the kidney pelvis is filled, as evidenced by pain or discomfort to the patient, and then making a pyelogram in both recumbent and upright postures, and, finally, partly withdrawing the ureteral catheter and filling the ureter, thus making another exposure which outlines both the pelvis and ureter. Some urologists use a large catheter to obstruct the lower ureter and inject the pyelographic medium until the entire tract is distended by backflow. That there is still a great difference of opinion as to what constitutes the proper procedure in performing urography is stressed by Hinman in his work on hydronephrosis when he says,

"Authorities differ as to the relative value of the different methods used in making ureteropyelograms."

In spite of the fact that X-ray has been used all these years to aid in making urologic diagnoses, the fact remains that, as it is generally used to-day by the majority of men, the X-ray does not give all the information which should be had from such a procedure or all that is essential to a complete understanding of the pathology of the upper urinary tract. Pyelography, while absolutely essential, as routinely done shows only the anatomical form or morphology of the urinary tract. Furthermore it is often necessary to repeat the examination because of some obscurity or baffling appearance. If the case is one of advanced pathology, then knowledge of gross anatomic change is probably all that is needed. But, in the great majority of cases, it is absolutely essential that a definite knowledge be had of the physiology or motor function as well as of the anatomic form in order properly to prognosticate and treat the case. Thus, to enable one to apply the correct therapy, a complete X-ray diagnosis must include a study of the physiology or motor activity of the pelvis as well as its morphology. Must one wait until there is gross tissue change before one can apply the proper treatment? What is therapeutics? According to Billings, "Therapeutics is largely an effort to convert pathologic into normal physiology. Intelligent therapeutics and pathologic physiology should go hand in hand." Thus, a knowledge of the form as well as the physiology of the pelvis and ureter can be obtained only by combining a motor functional study with pyelography.

The physiology of the pelvis and ureter is

analogous to that of the stomach and duodenum. They are both contractile organs endowed with a motor activity and a sphincteric function. The physiology of the pelvis is characterized by a succession of movements or contractions and relaxations, opening and closing of sphincters in a harmonious way and at a precise time. In nephrectomized kidneys preserved in saline, it has been observed that the kidneys contracted at times spontaneously but could be excited to contractions by mechanical stimulation either of the ureteral stump, pelvis, or calices. These excitations produced the following movements: the pelvis is first in diastole, or relaxed, extending beyond the renal sinus. By stimulating the stump of the ureter, the pelvis is caused to contract and withdraw itself up into the renal sinus, where it disappears, drawing the ureter after it. Presently one sees the pelvis slowly relax, little by little, and at the same time, a wave is produced in its inferior extremity and is propagated to the stump of the ureter, which executes a creeping movement. Then follows a sharp phase of inexcitability which continues for a variable period of time after each contraction.

Clinically, this phenomenon is beautifully demonstrated in the normal pelvis by injecting a pyelographic medium under fluoroscopic vision and, while the pelvis is filled (but not to the point of distention and production of pain), withdrawing the catheter and observing its contractions. One notes the following: besides the large respiratory movements, on close observation there is to be seen a wave of contraction progressing from calices to pelvis which carries with it part of the opaque liquid in the calices and causes them to appear more dense. This wave of contraction then spreads over the pelvis and forces some of the fluid into the bulb, that small portion between the pelvis above and ureter below, which has been closed until this time by the supra-bulbar sphincter. None flows into the ureter since

at this moment it is closed by the infra-bulbar sphincter. At the time of filling the bulb, the systole of the pelvis, coinciding with the diastole or relaxation of the calices, produces a refilling of the calices. Also at the end of this period a second wave, or the first one momentarily arrested, beginning in the bulb, forces open the infra-bulbar sphincter and continues rapidly down the ureter to the bladder. The bulb remains visible generally for from two to three seconds. The supra-bulbar sphincter prevents reflux into the pelvis as well as emptying of the pelvic contents into the ureter. This process continues until the pelvis is empty. Masses in the amount of 1/10 c.c. are forced periodically from the bulb into the ureter. These masses appear from 3 to 10 seconds apart and pass rapidly down the ureter, outlining its curves and contractures. The pelvis normally empties its 5 to 10 cm of injected material at the rate of approximately 1 c.c. per minute.

In studying the physiology of the pathologic pelvis, one notes abnormal fillings. Reflux around the catheter back into the ureter is abnormal if the tip of the catheter is well within the pelvis. This condition is often due to errors of technic, such as too rapid injection, or to the injection of too much liquid, resulting in acute pelvic spasm and production of severe pain in the patient. These errors immediately render further functional studies useless since they induce an abnormal physiology. This reflux is also seen where the sphincters are insufficient. In these cases, the opaque fluid runs down the ureter as the injection is in progress.

We next study abnormal modifications in evacuation, paying especial attention to the bulb, particularly noting its situation. It normally connects the inferior medial border of the pelvis with the ureter. It may be irregular and contorted due to peripelvic sclerosis, or one might see a notch or constriction running through it, caused by an

abnormal artery. This defect persists throughout the examination, but none of these deformities in themselves constitutes a disturbed motor function. Thus, in order to make a correct diagnosis, one must observe the entire picture and not an isolated finding, based on a single pyelographic plate. The bulb, as previously remarked, is formed normally every 3 to 8 seconds. If the evacuation be retarded, this rhythm is interfered with and the time between "bulbs" is prolonged. Yet, however retarded this rhythm may be, as a general rule the bulb empties itself promptly. Again, one at times sees a complete or incomplete loss of sphincteric power, in which case the liquid either flows or dribbles into the ureter more or less continuously. Here, however, one finds the evacuation retarded because of pelvic inactivity.

In considering abnormal modification of contractions of the pelvis, the degree of their intensity is of most importance. They may be either very active or completely abolished in a pelvis the walls of which are rigid and sclerosed. In discussing abnormal passage of the liquid through the ureter, Legueu says that in some cases stricture, kinks, calculi, etc., cause a mechanical stagnation and dilatation above the obstruction, but in most of these cases it will be impossible to pass a catheter by the obstruction. If the catheter passes and one succeeds in filling the pelvis, one sees after its withdrawal either a normal evacuation or pelvic retardation. If there is pelvic retention, it is not mechanical but reflex and one sees neither pelvic contractions nor bulb formations. Moreover, there is no accumulation of liquid between the kink or apparent obstruction and the pelvis. Finally one judges the time of pelvic evacuation by a study of the mode of formation of the bulb as well as the motility of pelvis and calices. The normal evacuation presupposes a harmonious equilibrium between two elements, the force which propels, i.e., the

contractions of the pelvic musculature, and the force which holds in check or rules over the intermittent discharge, i.e., the pyelo-ureteral sphincters. The pathologic modification of the play of these two forces which brings about different degrees of impaired motility in the upper urinary tract. These variant degrees of disturbed motor activity may be classified as incontinences and retentions.

1 Complete pelvic incontinence is rare and is seen only in cases in which the pelvis and ureters are sclerosed, as in advanced tumor formation, in some cases of primary infection, and in some congenital dilatations. The fluid runs out into the bladder immediately after the catheter is withdrawn. One sees neither pelvic contractions nor bulb formation. In this type of case, one could get good pyelograms by filling the bladder with fluid and producing backflow into ureter and pelvis.

2 Where there are insufficient sphincters, the fluid immediately on injection flows into the ureter almost continuously. No definite formation of bulbs is seen and the flow of liquid is only temporarily interrupted from time to time. The evacuation is, however, prolonged since the pelvic contractions are very feeble. This type is similar to chronic incomplete retention and is seen in a large number of pyelonephritic cases.

3 In a very rapid evacuation or hyperkinetic pelvis, contractions are very strong, the bulbs are rapidly formed, and the pelvis is emptied very quickly. These cases, which give a history of marked vagotonia with attacks of renal pain, are benefited by the use of belladonna. We have recently seen a case of this type respond to this treatment. This class is very closely allied to acute spasm.

4 Under the heading of chronic incomplete retention, one finds several degrees of retention slight retardation of evacuation characterized by slow formation of bulbs

and prolonged evacuation time, retarded evacuation with insufficient sphincters as mentioned previously, incomplete retention with residue where the evacuation starts out normally, but bulb formations become further and further apart and finally cease altogether, leaving a residue in the pelvis or calyx, Crabtree's intermittent retention seen in movable kidneys, where one finds stasis during renal ptosis but, on relieving the ptosis, contractions are established. This latter test is the only true indication for nephropexy.

5 In chronic complete retention, the liquid remains in the pelvis for many hours and is finally diluted by secreted urine.

6 Acute spasmodic retention, due to errors in technic when a small pelvis is forcibly over-distended, occurs repeatedly when pyelograms are made blindly, and the patient is caused much needless pain and suffering.

Study of the physiology of the pelvis and ureter has pointed out the fact that a dilated pelvis is the result of an impaired motor activity. It is not in itself a primary condition. If it is dilated to such an extent that a diagnosis of hydronephrosis can be made from a pyelogram, then it will certainly show a markedly impaired function. More than this, functional studies by fluoroscopy will show an impaired motor activity or retention long before dilatation can be determined. Dilatation or anatomical change is slow to progress and only secondary to retention, which is influenced reflexly and changed readily. Dilatation and retention both represent an alteration of the pyeloureteral muscle but atony or dilatation is a stable state which changes slowly, while the motor activity represents the actual state of muscular contraction at a given time. It is true that the more marked the distention, the more deficient the motor activity. That the impaired function is primary is seen in types accompanied by small hydronephrosis with little or no distention, but having at-

tacks of renal colic and a hyperkinetic pelvis, or in cases with incomplete retention. Here the deficient muscular activity produces retention which later leads to atonicity or dilatation. It is an established fact that the motor activity of the renal pelvis is very quickly influenced by reflex. This has been proved many times in cases of renal calculi, abnormal arteries, etc., in which the stasis rapidly clears up after removal of stone or section of an artery. From a prognostic view, let us point out the fact that a pelvis not dilated but having incomplete retention progresses slowly to dilatation and atonicity unless the cause of the retention is removed. On the other hand, a dilated pelvis which evacuates itself sufficiently is one in which the dilatation will improve as time goes on. To be of prognostic value, a functional study must show not only whether there be retention but also to what degree retention has progressed. Thus X-ray studies, to be complete, must show us the physiology as well as the gross anatomy of the pelvis. Ureteral catheterization demonstrates the bacteriology. Infection and distention of the pelvis do not progress equally. In fact, infection may mitigate against distention by producing sclerosis of the pelvic walls, however, the degree of infection and retardation in evacuation of the pelvis go hand in hand.

It is admitted by all that stasis is the prime factor in the perpetuation of the great majority of kidney infections. It is the bugbear of urologists. The treatment of kidney infection is, therefore, largely the correction of those conditions which cause stasis. Pyeloscopy not only shows the degree of stagnation, which is of prognostic value, but points out the causative factor, be it stone, kink, excessive mobility of the kidney, stricture of the ureter or other cause. After this causative factor is removed, the motor function soon returns to normal and then the infection responds readily. Bear in mind that this deranged motor activity is

often reflex and the pyelographic plate will show a pelvis practically normal in size and contour, but the fluoroscope will point out the fact that it is not functioning properly Pelvic lavage will never clear up a pyelonephritis unless the motor activity of the pelvis is normal When normal physiology is established, even gross pathologic anatomy will in time return to an almost normal condition, if too much permanent damage to the kidney parenchyma has not been done

From a therapeutic viewpoint, pathologic pelvis may be placed in two classes

1 *Primarily Aseptic*—Motor functional impairment is primary yet trophic disturbance or dilatation progresses along with it If infection is added to this weakened organ, pyonephrosis readily follows In this type, which includes the great majority of chronic pyelonephritic cases, the cause of the retention must first be discovered and removed, following which the infection is readily overcome

2 *Primarily Infected*—Here the normal pelvis is infected and, instead of large dilatations, one sees sclerosis, which likewise brings about disturbed function The two thus work in a vicious circle If the retention is complete in this type of pelvis, one had best do a nephrotomy and put the pelvis at rest If it is impaired to a relatively slight degree, lavage may bring about cure

CONCLUSION

May we emphasize the fact that fluoroscopy is essential in making an X-ray study of the kidney, for by it we—

1 Fill the pelvis sufficiently but never over-fill, thereby causing the patient severe pain

2 Clear up obscurities by noting them during the examination, when they can be studied, and not later when pyelograms are being viewed Under vision the kidney may be palpated, thus its mobility, relation to stone, foreign bodies, tumor, etc., may be noted

3 Take pyelograms or permanent records of observed stages of pelvic activity and do not work blindly as in the past

4 Learn what pyelography alone can not show us, that is, determine the physiology of the pelvis at the time of examination and point out the causative factor if its motor activity is impaired By so doing, we render the examination truly scientific and save our patient much pain and suffering and, indeed, even prevent the possible loss of the kidney itself It is not a difficult feat to remove a destroyed pyonephrotic kidney but how much better it is to correct disturbed function in its incipiency and to prevent destruction of the kidney This then must be the service the roentgen laboratory can render the urologist in the future

FRACTURES AND INCOMPLETE DISLOCATIONS OF THE MANDIBLE OR MAXILLA

By LLOYD ROGERS, D.D.S., C TAYLOR HALL, D.D.S., and
JOHN H SHACKELFORD, D.D.S., DETROIT, MICHIGAN

LET us say at the outset that it is not our intention to impose our methods upon others. Our only intention, indeed, is to attempt to give some practical instruction on the subject of fractures—a subject which has, in the last few years, been one of increasing importance to the dental, as well as to the medical, profession.

While our method of treating fractures is neither new nor complicated, the results obtained have been highly gratifying. And we believe we may be pardoned the assumption that if results are satisfactory, the methods employed must be worth some consideration.

FRACTURES

During the past sixteen years we have seen and treated a large number of fractured jaws. In 1928 our clinic extended services to 312 patients, in 1929 this number was increased to 376 patients, and in

1930 to 482. Of this number, 94 per cent were treated for fractures of the mandible, the remainder for fractures of the maxilla.

Detroit, curiously enough, seems to have earned a reputation for skull and jaw fractures. This phenomenon may be partly attributed to the fact that, being the motor center of the world, rapid transportation here is on a steady increase, bringing in its wake an inevitable and concomitant increase in accidents. As a matter of fact, Detroit has more automobile accidents, *per capita*, than any other city in America, and automobile accidents appear to be the chief contributing cause of fractures.

Next to vehicular accidents, John Barleycorn must come in for a substantial share of the blame. Intoxication leads frequently to fights, and fights to broken jaws. Add to these the occasional meetings of skull and black-jack, falls, gunshot wounds, and numerous other accidents which occur readily

Fig. 1 Gunshot fracture of mandible and maxilla.

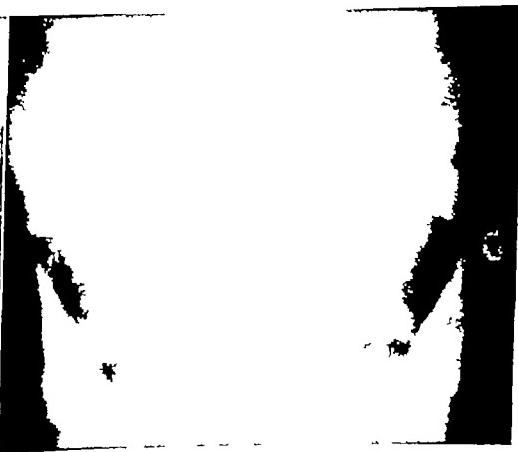

Fig. 2. Head of condyle destroyed by gunshot.

Fig 3 Gun slug fracture of mandible, with large facial wound

Fig 4 Fracture of mandible, showing the usual condition from non-treatment or no immobilization

in a large city, and it is easy to see how the number of fractures grows

It has been our observation that many fractures of the jaws are overlooked. For example, a patient is taken to a hospital from the scene of an accident. He is probably unconscious. At the receiving room a diagnosis of probable skull fracture is made, and X-ray films are ordered. The X-ray department makes the radiographs of the skull but neglects to examine the jaws. Even when the jaws are examined, a fracture in the condyle region may be missed and too often we find a fracture of the maxilla undiagnosed, especially in the edentulous patient.

In our clinic at the Receiving Hospital, Detroit, all patients with head injuries are given an X-ray examination for jaw fractures, and in many cases we advise a postero-anterior plate to determine whether or not the patient has a fracture in the condyle region. For this purpose right- and left-angle jaw plates are always taken. If any doubt remains, the roentgenologist orders a digital examination in the oral surgery department, regardless of whether the patient is in the hospital or the Out-patient Depart-

ment. We hold it inexcusable for the hospital to release a patient with an overlooked fracture of the jaw. All too frequently hospitals do release such patients. At the time of this writing, for instance, we are treating the wife of a prominent citizen of this city for a fractured jaw in the condyle region. Following an automobile accident, this patient had been hospitalized in a first class hospital for ten days, where she was treated for sprain and abrasions. Although X-ray films were taken of the skull, jaws, arms, and legs, the fracture of the mandible was not found. The woman complained of pain in the jaws, but jaws and skull remained negative in the diagnosis. We mention this in no derogatory manner, but offer it as constructive criticism. Too much care can not be exercised in our examination of these patients; jaw fractures should be detected before the patient is released from the hospital.

PRINCIPLES OF TREATMENT

The fundamental principles employed in the general treatment of fractures may be applied, with some modifications, to the re-

Fig. 5 Simple fracture of the rami of the mandible through the sigmoid notch. Treatment was conventional immobilization.

Fig. 6 Fracture of the rami of mandible through the sigmoid notch with displacement of condyle. These cases usually require a general anesthetic for relaxation and manipulation.

duction of fractures of the mandible and maxilla. These are:

1 Diagnosis from X-ray findings. General physical and oral examination.

2 Reduction of the fracture, or fractures, and possible manipulation for the fracture at the head of the condyle, or where there is an overlapping of the fragments.

3 Fixation of the parts splints (silver wire open reduction), interdental wiring, Barton's, or plastic Barton casts.

4 Post-operative treatment.

5 The use of exercising splints, in some cases, to restore the function of mastication and to hasten the return of normal muscular tone. Likewise, in a few cases, orthodontic appliances to restore normal occlusion.

CONSIDERATIONS BEFORE REDUCTION

First, for the benefit of the doctor, and as a matter of record, the patient should always be subjected to X-ray examination before reduction is attempted. The oral cavity should be made as clean as possible,

and all septic material, such as deposits of tartar and diseased roots, should be removed. All abrasions and wounds should have surgical treatment, according to the requirements of the individual case.

Many surgeons advise the removal of teeth and roots found in the line of fracture. In our experience, however, we have found that this procedure is not always advisable, and indeed, in many cases, actually contraindicated. We can show records of fractured mandibles in which such teeth have held the fractured portion of the mandible in the correct position, aiding us in obtaining the final anatomic relationship desired in the reduction of the fracture. Another factor to be considered is that sometimes the removal of these teeth is the cause of osteomyelitis, due to the frequent occurrence of considerable trauma in extraction. Many of the retained teeth are extracted later (possibly after a period of ten days). By this time they will have served their purpose, especially in fractures of the mandible at the angle, in which instance the posterior

fragment would tilt upward or forward were these teeth not retained

In a case, however, in which there is a tooth that prevents the approximation of the broken fragments or otherwise inter-

dental wiring because of the danger of shock and strangulation Reduction can be accomplished just as effectively later, without taking chances

Other important considerations in the

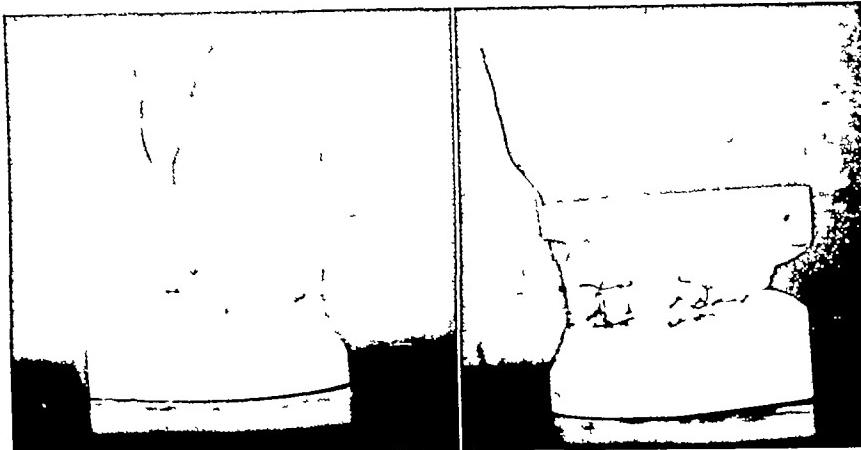

Fig 7 Interdental wiring

fers with bone alignment, we do not hesitate to advise extraction such a tooth should be removed

In gunshot fractures it should be remembered that when a bullet stops going it stops doing damage The spectacular operation for the removal of such a foreign body is rarely, if ever, warranted The patient should be allowed to recover from the shock, as often more damage is done in trying to remove the bullet than had it been forgotten Should, however, any metallic pieces from a spattered bullet be in line of fracture, or if the bullet or fragments of bullet or bone can be visualized or removed without a great deal of destruction to the surrounding tissue, then they should be removed

Jaw fractures associated with other complications, such as skull fracture, injuries to the chest, etc., require a few days of complete rest before an attempt is made to reduce the fracture It would be unwise immediately to start immobilizing with inter-

treatment of fractures are sequestra, cysts, impacted teeth, and possible growths Recently a patient presented himself, stating that he had a broken upper jaw Upon examination, we saw the largest fibroma on record in the mouth—it measured seven inches in circumference and weighed 131 grams It was attached to the roof of the mouth in the upper left molar region, and also across the roof of the mouth at the anterior border of the soft palate It was highly vascular, but not malignant The growth had caused considerable pressure atrophy, and the maxilla on the left side had become so weak that a very slight blow had been enough to cause the fracture

REDUCING THE FRACTURE

Occlusion—In reducing a fracture in an instance in which the teeth are present, careful attention must be paid to their occlusion This feature is most important, for, if overlooked, even if there is union of

Fig. 8-A Patient with fractured maxilla and large fibroma

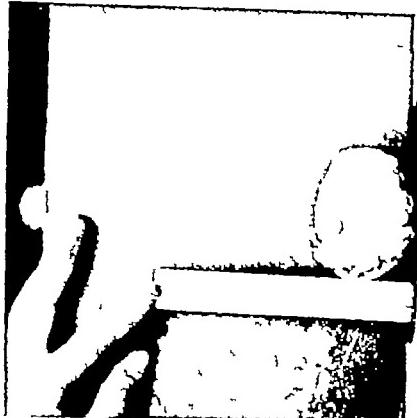

Fig. 8-B Fibroma 7 inches in circumference removed from patient's mouth

bone, the results will be unsatisfactory. If the teeth can be placed in normal occlusion or in the manner in which they occluded before the jaw was fractured, and can be retained in that position long enough for osseous union, the results will be satisfactory.

Anesthetics—Often a fracture may be reduced without anesthesia, with practically no pain. In cases in which anesthesia is indicated, we prefer the use of conduction rather than general anesthetics. With the former we are able to secure the co-operation of the patient, and have very little, if any, vomiting or nausea with which to contend.

When a general anesthetic is employed, we usually place the interdental wiring loops on the teeth before administering the anesthetic. After the patient has been anesthetized, we do such surgery or manipulation as is indicated. When the patient has sufficiently recovered from the effects of the anesthetic, the teeth are placed in occlusion and the connecting wires passed through the loops and twisted into place.

Interdental Wiring—Interdental wiring is the best method for immobilizing fractures of either the maxilla or mandible. The teeth are always placed in normal or original occlusion. If this is not accom-

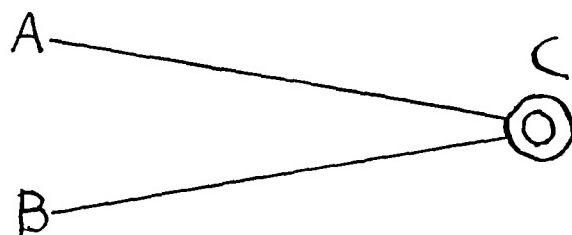

plished at the first sitting, the teeth will usually pull into position when the wires are tightened the second or third day, and the muscles of mastication will always be at rest. When the teeth are placed in original or normal occlusion the fragments of the bone must be in correct anatomic position, when the teeth are present no fracture requires more accuracy in reduction than that of the mandible.

The advantages of interdental wiring are—

- (1) Normal or original occlusion, correctness of median line, and harmony of facial expression are obtained.
- (2) Only a few instruments and 28-gauge wire are required.
- (3) Interdental wiring requires less time than the making of splints.
- (4) Interdental wiring is not annoying to the patient.
- (5) Interdental wiring is the most accurate and dependable of all methods.

Method of Interdental Wiring—Our favorite method for reducing fractures of the mandible is to support the mandible (teeth in occlusion) to the maxilla from three points—the bicuspids, or first molar region, on each side of the mouth, and the centrals in the anterior portion.

A piece of wire, 26- or 28-gauge, 10 inches long, is doubled and twisted around a small round instrument (a wooden applicator is a good size) about two or three turns, producing a small loop or eyelet at the end of the wire where it is doubled

The wire is now taken and the two ends ("A" and "B") are inserted at the buccal surface, passed from the buccal to the lingual surface, and then pulled through between the second bicuspid and the first molar, leaving the eyelet ("C") protruding a little just buccalward of the soft tissue between the two teeth. The wire ("A") is then pushed from the lingual to the buccal surface between the first and second molars, is pulled tight, and passed through the eyelet ("C"). The wire ("B") is passed

from the lingual to the buccal surface between the first and second bicuspids and pulled tight. With a small blunt instrument, the wires are pushed well up on the necks of the teeth and the two wires ("A" and "B") are twisted to the right and pulled outward at the same time until they are firm and secure. Our rule of twisting all wires to the right has proved helpful to us at our clinic. In cases in which some slight adjustment is necessary, whoever is on duty, whether he has seen the patient before or not, knows that wires always are turned to the right. We have found this rule very helpful.

The other wires are placed below in the same manner and on the opposite side and the anteriors passed between and around the centrals. We are then ready to occlude the mandible with the maxilla. Usually two wires are passed through the loop on the upper and then through the loop on the lower teeth (Figs 7-A and 7-B). The teeth are brought into correct relationship, and the wires are twisted tight by a turn to the right and a gentle pull outward. The wires

Fig. 9 Fracture of the mandible with posterior fragment tilted forward and upward.

Fig 8-A Patient with fractured maxilla and large fibroma

Fig 8-B Fibroma 7 inches in circumference removed from patient's mouth

bone, the results will be unsatisfactory. If the teeth can be placed in normal occlusion or in the manner in which they occluded before the jaw was fractured, and can be retained in that position long enough for osseous union, the results will be satisfactory.

Anesthetics—Often a fracture may be reduced without anesthesia, with practically no pain. In cases in which anesthesia is indicated, we prefer the use of conduction rather than general anesthetics. With the former we are able to secure the co-operation of the patient, and have very little, if any, vomiting or nausea with which to contend.

When a general anesthetic is employed, we usually place the interdental wiring loops on the teeth before administering the anesthetic. After the patient has been anesthetized, we do such surgery or manipulation as is indicated. When the patient has sufficiently recovered from the effects of the anesthetic, the teeth are placed in occlusion and the connecting wires passed through the loops and twisted into place.

Interdental Wiring—Interdental wiring is the best method for immobilizing fractures of either the maxilla or mandible. The teeth are always placed in normal or original occlusion. If this is not accom-

plished at the first sitting, the teeth will usually pull into position when the wires are tightened the second or third day, and the muscles of mastication will always be at rest. When the teeth are placed in original or normal occlusion the fragments of the bone must be in correct anatomic position, when the teeth are present no fracture requires more accuracy in reduction than that of the mandible.

The advantages of interdental wiring are—

- (1) Normal or original occlusion, correctness of median line, and harmony of facial expression are obtained.
- (2) Only a few instruments and 28-gauge wire are required.
- (3) Interdental wiring requires less time than the making of splints.
- (4) Interdental wiring is not annoying to the patient.
- (5) Interdental wiring is the most accurate and dependable of all methods.

Method of Interdental Wiring—Our favorite method for reducing fractures of the mandible is to support the mandible (teeth in occlusion) to the maxilla from three points—the bicuspids, or first molar region, on each side of the mouth, and the centrals in the anterior portion.

different teeth at the gingiva, and twisting the wire tight around the bar. The bar may be attached to several teeth to hold the fragments and the teeth in correct position in the arch. Sometimes, if necessary, bars are used on both sides of the teeth, and are attached to the teeth in the maxilla and the mandible. After these bars have been attached so that the arches correspond and the teeth can be placed in occlusion, the mandible is attached to the maxilla, the 28-gauge wire being passed over and around the bars on the buccal and lingual surfaces, the wires being twisted tight, as previously described in interdental wiring.

Post-operative Care.—The average fracture requires four weeks in which to unite. We have had excellent results in three weeks, while other cases have required as many as nine weeks.

Although we have tried all kinds of special diets and light therapy to make bone unite more rapidly, none has proved very satisfactory.

We insist on a mouth wash every three hours. We see the patient usually every two or three days, if necessary, every day.

We employ aniline dyes, crystal violet and brilliant green for post-operative treatment, followed by a saline mouth wash. For this purpose sodium perborate (saturated solution) is prescribed.

FRACTURES OF THE MANDIBLE EDENTULOUS

Some operators prefer taking impressions and making vulcanite base plates for splints, adding the vulcanite bite rims, wiring the splints together by drilling holes through the rims and fastening them together with wires. In the central region the vulcanite bite rims can be omitted for the passage of nourishment, and the Barton plaster cast used over the head to immobilize the mandible with the maxilla. If the patient has dentures, holes may be drilled in the den-

tures, and then wired together. These make excellent splints.

Circumferential Wiring.—In this case only the base plate can be used. Silver wires

Fig. 13 Multiple fractures with severe facial lacerations

are passed through the soft tissues, one on each side of the fracture, under and around the mandible (intra-oral), and twisted tight over the base plate, holding the fragments in alignment with the base plate.

Open Reduction (Intra-oral) for Fractures of the Mandible (Edentulous Cases).—We have used the following method extensively and have found it satisfactory, therefore, we prefer it to other methods. In cases in which teeth are not present, an incision is made on the superior border of the mandible, extending two or three inches distally and mesially of the fracture. With a periosteal elevator the tissue is flapped back, exposing the bone at the point of fracture. The two ends are raised up and a surgical

Fig. 11 Fractured mandible, third molar in line of fracture

Fig. 12 Fracture of mandible in region of angle showing muscle pull

are then cut short and turned in so as not to interfere with cheeks or lips. All wires must be kept tight so that they will not slip.

In wiring the mandible to the maxilla in this manner it is a very simple matter to cut the three wires, if for any reason the mouth has to be opened. Only a few minutes are required to pass new wires through the same eyelets and retie the teeth in occlusion. Lacing the two teeth together as described, with "A" and "B" wires, to hold the eyelet in place, offers less opportunity for loosening of the teeth than if single teeth were used.

When the fracture of the mandible is in the condyle or sigmoid notch region, frequently the muscles will pull this fragment outward, sometimes forward, perhaps inward, even after the interdental wiring has placed the teeth in occlusion. If the distal fragment has moved outward, we advise an extra-oral splint or a plastic Barton ban-

dage, with a gauze sponge or other soft pad under the splint or Barton bandage at the location of fracture to act as a depressor until union has begun.

In fractures of the maxilla we employ the same method of interdental wiring, while with plastic Barton bandages we mold a plaster cast which holds the mandible against the maxilla. We have applied this method with good results in cases in which the maxilla has been fractured through both orbits and the nasal sections, allowing it to drop downward.

In cases of multiple fractures of the maxilla or mandible, we often use the small size bar, such as is used for a lingual bar in prosthodontia, or medium piano or platinum wire, shaping this to fit the arch of the mouth just labial to and buccalward of the necks of the teeth. It is then laced with 28-gauge wire to the necks of the teeth by passing the wire around the necks of the

Fig. 17 Barton plaster cast.

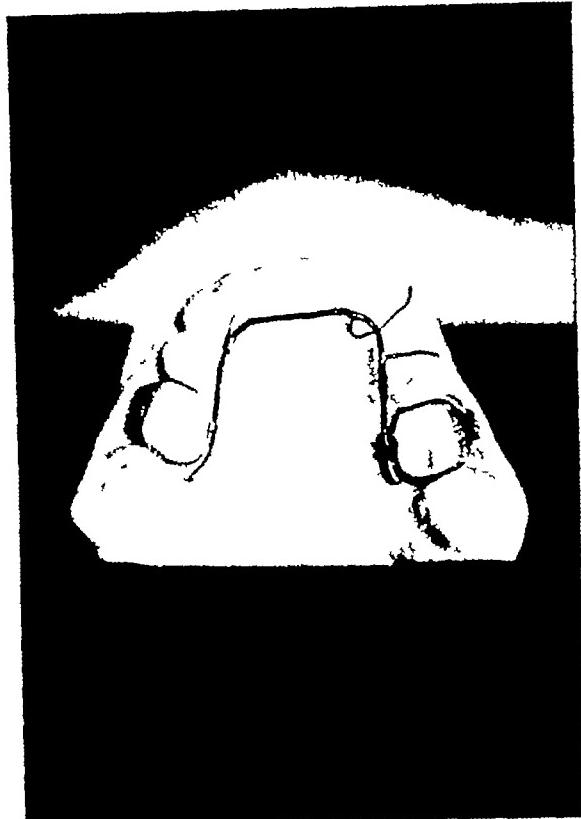

Fig. 18 Orthodontic splint used to correct and retain occlusion

ever possible, but seldom can wires be attached to the deciduous teeth. In many cases, the child will not be old enough to have teeth which can be used for interdental wiring. In these cases the fracture is reduced and held in position with Barton's bandage. A thin Barton may be used for a pad, over which adhesive 1 or $1\frac{1}{2}$ inches in width is applied. First the Barton and then the tape is passed under the chin and over the head, and then around the base of the head and forehead to keep the Barton from slipping forward or backward.

Fractures of the mandible that have not had professional treatment for several days, weeks, or even months are not uncommon. In some cases a Barton bandage may have been placed under the chin and over the head in such a manner as to cause an overlapping of the fragments. A fibrous union

has possibly started, with fragments out of alignment. The best results in these cases are obtained by removing the fibrous tissue and exposing the ends of the fragments, which are then freshened with a large burr or file. The flaps are returned and sutured into place, followed by the usual procedure of immobilization.

We have seen several cases of fracture of the mandible in which the head of the condyle has been completely destroyed by gunshot. Treatment of these cases is usually governed by the amount of damage or destruction caused by the bullet or slugs. Infection may or may not be present. The wound may be almost closed, or large and open, depending upon the size of the bullet or slug and the distance from which it was fired.

When a small bullet, such as a 32- or 38-

Fig. 14 Multiple fracture of maxilla and mandible

burr or drill is used to drill two holes in each fragment, one at the superior border and

Fig. 16 Intra-oral open reduction, 20-gauge silver wire

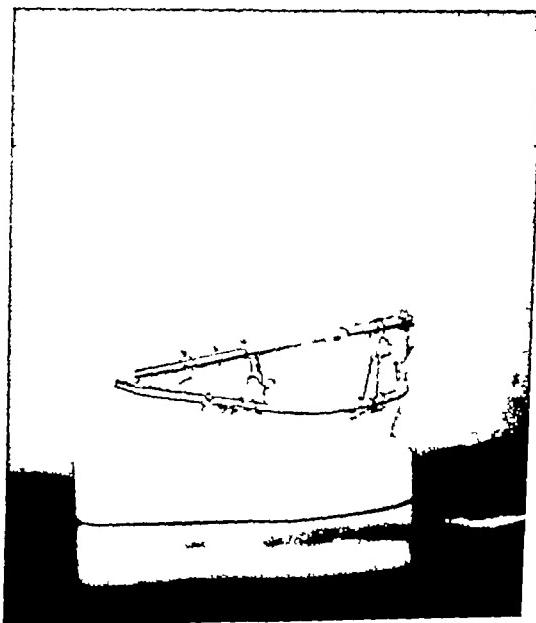

Fig. 15 Wiring method for multiple fractures of mandible or maxilla.

one at the inferior border of each. Two silver wires, 20- or 22-gauge, are used, one of which is passed through the superior hole of the mesial fragment and then through the inferior hole of the distal fragment. The other wire is passed through the superior hole of the distal fragment and then through the inferior hole in the mesial fragment. The ends of the bone are brought into anatomic relationship and the wires are twisted just tight enough to hold the fragments together. Now the surplus wire is cut, the ends are smoothed, and pressed against the bone. The flaps are put back in place and sutured. The usual post-operative treatment then follows.

We have had patients 60 and 65 years of age, all of whom have made excellent recoveries from fractures of the mandible that have been treated in this manner. While we are aware that some surgeons prefer to use this method extra-orally, we believe that it is seldom, if ever, indicated.

In treating children for fractured jaws, the interdental wiring should be used when-

specialist finds nothing wrong with the ear or adjacent structures. This condition is very puzzling to the doctor who may not be familiar with it. In these cases, the patient's mouth should be examined for the loss of teeth, improper articulation, and false movements of the mandible.

Slight unilateral dislocations of the temporal mandibular articulation are quite frequent, in fact, they might be classified as common. However, due to the fact that the pain or discomfort resulting from this is usually mild (in only a few cases is the pain very acute) and that this condition usually subsides without treatment, little or nothing is found in the literature on the subject. Often when patients complain of this discomfort, other causes are looked for, and frequently such diagnoses as neuralgia, arthritis, and myositis are made. The chief complaint in these cases is a radiating pain throughout the temporal region, greatly aggravated during movements of the lower jaw.

The nerve supply to the temporal mandibular articulation is derived from the auriculotemporal and masseteric nerves, the latter constituting a branch of the mandibular division of the fifth nerve, which communicates with the facial nerve.

When the lower jaw is depressed to a great extent, the interarticular cartilage is drawn forward and the capsular ligament may be injured, or even ruptured. Causes of dislocation of this nature include yawning, convulsions, undue pressure with mouth gags, choking and vomiting, and the taking of too large bites.

Another class of partial dislocation is that in which the displacement is forward and lateral. The teeth may have been worn smooth and the patient may favor biting on one side, there may be unilateral absence of teeth, compelling the patient to use but one side of his mouth for mastication, dental restorations may be too high or too low, resulting in a slight backward dislocation. In

Fig. 21. Fracture of the maxilla through the nasal and both orbital regions.

these latter cases the interarticular cartilage is usually injured. The teeth will be found to have been worn down to allow the lower jaw more nearly to approach the upper when the jaws are closed. Also, plates are made which prevent the jaw from assuming its natural position at rest. In edentulous cases in which plates are not worn, another cause may be found in systemic conditions which result in loss of synovial fluid.

It would seem that nearly everyone might be suffering from some discomfort in the temporal mandibular joints, however, this is not the case and usually dislocations do not occur unless the enumerated causes are quite exaggerated or the ligaments have been severely injured at some time, causing four of them to lose their tone. Patients complaining of this pain usually give a history of former injury. They also complain of having had slight neuralgic pain. In other words, the pain continues to be intermittent unless the cause is determined and corrected. At examination, the patient is required to open and close his mouth, disclosing the fact that the lower jaw drifts ever so slightly to the unaffected side.

Treatment consists in manipulation of the jaw to release any tissue within the joint and the carrying of the interarticular cartilage to its proper place between the condyle

Fig 19 Fracture of mandible Third molar holds distal fragment in position

Fig 20 Fracture of the mandible, showing considerable loss of bone, due to lack of immobilization

caliber, has entered the condyle region, with destruction of the head of the condyle and with no infection present, if the location of the bullet is non-vital, we have found it advisable not to disturb or open this region. Nor do we immobilize these cases, as we wish to form a pseudo-articulation or a false joint. The patient is put on a liquid diet, followed by a soft diet, then, in two or three weeks, a normal diet. The continual movement thus provided during the healing process prevents ankylosis from taking place.

With gunshot fractures of the mandible, in which the head of the condyle has been destroyed, the laceration of the tissue has presented itself within a few hours, our procedure is to sterilize the field of operation, remove all fragments of bullet and bone possible without further destruction of tissue, and, with a burr, smooth the head of the condyle or that portion of the bone which is left. Some of the fascia is then drawn over the smoothed head, being held in place with soluble sutures. Drainage should be established if indicated, or the wound closed. There is immobilization, and the same diet is ordered as for small bullet wounds.

INCOMPLETE DISLOCATIONS

Dislocations of the lower jaw are usually intracapsular because of the wide articular capsule which permits displacement without division of its surface, *i.e.*, dislocation in the most simple form. Through relaxed conditions, one or both condyles may lodge upon the intra-articular cartilage over the eminentia articularis. Relaxation of the external lateral ligaments and the enlargement of the articular capsule, with absorption of the anterior bony wall of the external auditory meatus, may be caused by loss of teeth, improper articulation, irregularity of teeth, or deformities of the maxilla. These conditions cause abnormal movement of the mandible and result in the enlargement and absorption of the capsule and adjacent bony structure of the glenoid fossæ.

When the joint capsule is relaxed and the surrounding muscles and ligaments have lost their tone, the condyle is allowed free movement and incomplete dislocation results. In these lesions, small parts of the articular cartilage are impinged, pain in the side of the head and in the ear often resulting. The patient then consults the otologist for relief, but, upon examination, the

INTRAVENOUS UROGRAPHY¹

By ROBERT E CUMMING, M.D., DETROIT, MICHIGAN

UROGRAPHY is an all-important part of diagnostic effort in the study of genito-urinary tract disorders. Roentgenologic examinations of the entire urinary tract are routine in every clinic and hospital, more common investigation of the genital tract, in both male and female, would be of great value and may safely be predicted. Lately Sargent has made exhaustive studies of the seminal vesicles and the vasa deferentia, and Jarre with his Cinex camera has shown interesting possibilities in serial work upon the uterus and oviducts. We are familiar with Belfield's immensely valuable seminal vesicle roentgenograms in connection with his vas puncture therapy. One has only to secure a few seminal vesiculograms to note the wide structural variations in these pouches, which, coupled with careful visualization of the vasa and their ampullæ, constitute graphic evidence of disease possibilities and have a potential secondary bearing upon the health of the patient concerned. The late B A Thomas, of Philadelphia, was another pioneer in vas injection work, while Rolnick has continued to further the efforts instituted by Belfield. I believe both urologists and roentgenologists should make use of genital-tract roentgenograms as a regular procedure, merging diagnostic with therapeutic measures.

As indicated, in order to give contrast shadows, corresponding in outline only, but of value in diagnosis, of the lumina of the genital and urinary tracts, some radioopaque substance must be present in the given lumen in sufficient quantity to fill that lumen at least reasonably well. For the genitalia, direct injection would seem the only possibility, and, until recently, that requirement for visualization of the urinary

tract has been fairly well obtained by means of liquid media introduced through catheters into either the ureter or bladder. From the time of the early perfection of this method, however, and in spite of its enormous success, urologists have predicted the development of some sort of intravenous administration of medium for contrast shadows. So finally after a period of colorful scientific investigation, including exhaustive experimentation, *intravenous urography* has come into its own. It is being used by all modern urologists, and independently by roentgenologists. I shall endeavor to show why it is not wise for these two groups to use the method independently of one another.

It is interesting to note that one of the sponsors of the most successful medium for intravenous urography was a pioneer with the older, or retrograde, method. I refer, of course, to von Lichtenberg, of Berlin, who, with Swick, brought us a safe and fairly reliable compound in uroselectan, the preparation in more or less common use today.

We have personally had access to it for more than a year, and our successes in intravenous studies have been largely with uroselectan. Another promising drug is skiodan, but, while we have had this in hand for a much shorter period, we are skeptical of its superiority. Its local and systemic reactions are mild to a point of non-existence, but at the present time we cannot depend upon it for good visualization. The third urographic preparation advanced for intravenous use is pyelognost, which was developed by Roseno, in Cologne, and, before uroselectan was available, was used rather extensively by him and others in Germany. I do not know of any extensive practice with this drug in America, but Jarre and I have used it in some sixteen cases, with re-

¹Read in abstract before the Grace Hospital Staff, February, 1931.

and the glenoid cavity. If the lesion is slight, manipulation, and instructions to the patient not to open the mouth wide for two days are usually sufficient. However, in se-

vere cases, the jaw should be manipulated, the teeth wired together by means of interdental ligation, and the jaw kept at rest for two weeks.

GROWTH-CONTROLLING EXTRACT BEING TRIED IN CANCER

A substance having remarkable powers of controlling the growth of living beings and of possible value in the treatment of cancer is being investigated in the laboratories of the Royal College of Surgeons of England and at King's College, London. The discovery is due to a young biochemist, J. H. Thompson, who has found that an extract of the parathyroid gland of cattle will restrict or prevent growth without endangering the health of the organism.

The most important application of this discovery lies in the treatment of cancer. It is being tested in several London hospitals

with very encouraging results. Sir Arthur Keith has further suggested that it may be of value in the treatment of the disease called acromegaly or gigantism which is due to abnormal functioning of the pituitary gland.

The effect of the extract was first observed on rats and rabbits, then on watercress. At the suggestion of Prof Julian S. Huxley it was tried on the axolotl, a form of salamander. In all these cases the growth-retarding effect has been very marked. Treated rabbits have remained at about half the size of their untreated brothers and sisters. The germination of watercress seeds is entirely stopped by a 20 per cent solution of the extract.—*Science Service*

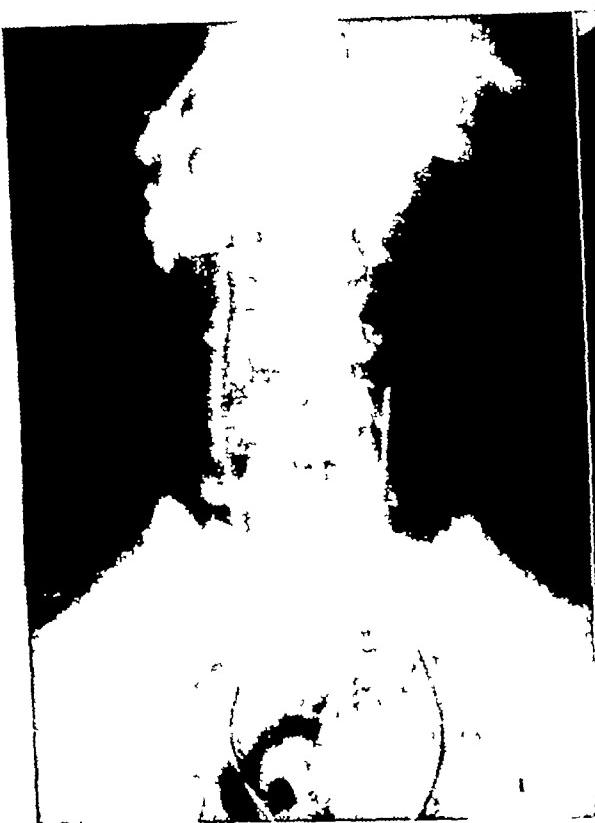

Fig 2-A Pyelo-ureterogram taken in 1927, showing pyelectasis with stricture at the uretero-pelvic junction

Fig 2-B The same case, 1931. Bilateral pyelo-ureterograms taken 30 minutes after the administration of skiodan. The 15-minute film showed excellent pyelogram of better kidney. Note the marked increase in hydronephrosis and failure of ureter to fill. This film is the best of the series for hydronephrosis demonstration

instrumentation incident thereto, does not often produce colic, which, in the absence of endogenous foreign matter, is brought about by local reaction following the introduction of a contrast medium. This reaction may be edema, spasm, hemorrhage, or a combination of these, and it occurs whether the injection is made with fluoroscopic control, although less often, or by the gravity method or the syringe method. One theoretic contrast is that catheter and retrograde media disturb physiologic activity, while intravenous media do not.

The particular boon of intravenous urography, then, is its applicability for patients who for one reason or another, cannot be subjected to ureteral catheterization, or in whom are found insurmountable mechanical difficulties. We may cite intolerant

bladder patients, those with severe vesical neck or ureteral obstructions, those with ureteral orifices in diverticula of the bladder, and those with transplanted ureters, as case illustrations of these types. Another, and important, type is the paralytic bladder group of cases, still fatally infected in most hospitals, in which data relative to the upper urinary tract are sometimes of importance. In this connection, it may be stated that even if a diagnosis in a given case can be made certain by intravenous urography, the later use of cystoscopic manipulations will, in a surprisingly large percentage of instances, be quite necessary.

Uroselectan, and probably skiodan, is apparently filtered through the glomerulus, and

Fig 1-A Complete urogram, 15 minutes after the administration of uroselectan in a boy aged 14 years, which shows recent injury of the urethra and fracture of the pelvis. Filiform stricture of urethra. Kidneys well preserved. Note distortion of ureters (kinks).

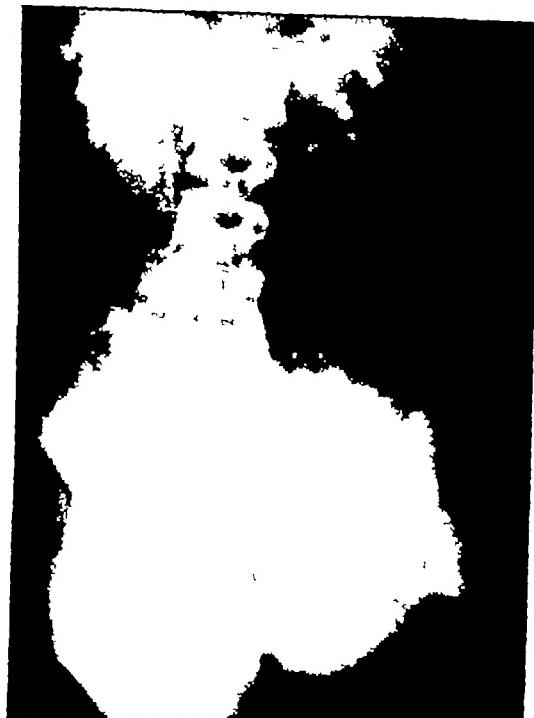

Fig 1-B Same case urogram made 15 minutes later. The pelvis and ureters are less distended and the ureteral kinks (?) have straightened. The earlier film is undoubtedly taken during "diastole," the second one probably during "systole," or at a period of lesser intrarenal activity.

sults which have heretofore been published, and which will be alluded to later in this paper. Suffice it to say here that we feel it to be definitely too toxic for wide usage, and less reliable as a medium for obtaining good roentgenograms than uroselectan or skiodan.

An important and natural question has arisen as to whether or not intravenous urography will supersede the older method. After we have placed so much faith in the latter for many years, is a new and relatively untried method desirable? The retrograde types of uograms are not perfect, while the newer ones, with an intravenous medium, in many instances, leave much to be desired. Intravenous urography, then, is not to displace the retrograde method, but rather to serve as an adjunct to it. From a different standpoint, intravenous urography was not

devised to make it easy for a roentgenologist to render a complete diagnosis in a case with a suspected renal lesion, although his analysis of the film series is of inestimable value, the new method is the product of urology, which in turn reaps the principal benefits of intravenous urography. These lie in the fact that a patient may be spared the added chance of a painful reaction to cystoscopy which is, of course, the necessary preliminary to retrograde urographic studies, except in a small percentage of cases. Also, in some types of cases, cystoscopy is unsatisfactory, and ureteral catheterization unsuccessful, and sometimes dangerous. Parenthetically we may be reminded that renal colic is due to obstruction in the transport passages of the urine, and that catheterization of the ureters, and the

Fig 3-4 Bilateral hydronephrosis, probably congenital Retrograde studies

Fig 3-B Same case in erect posture, catheters withdrawn Note the extreme rotation and ptosis on the right side Intravenous studies failed to demonstrate the degree of ureterectasis or any rotation

ular drug We are positive upon two points, namely, in normal individuals and in those with temporary or permanent cortical renal damage of an extensive nature, good, readable films cannot be at all regularly obtained It is in either of these two classes of individuals that the roentgenologist, independently, may be guilty of error in attempting a clinical diagnosis Careful selection of cases is necessary to avoid great waste of time and material in the practice of intravenous urography and one cannot anticipate with any degree of accuracy if in a given case satisfactory data may be provided Indiscriminate use of the method should be heartily condemned

A weakness related to the intravenous technic lies in its lack of aid in determining the so-called emptying time of a renal pelvis and ureter At the present time when so much stress is being put upon conservative renal and ureteral surgery, in connection with ptosis hydronephrosis, stricture, and

anomalies, the details of physiologic activity are important In a recent case of bilateral hydronephrosis with extreme ptosis and tenacious infection, our point of departure upon operative interference depended largely on our finding a marked delay in the emptying time of each pelvis After both kidneys were suspended, the infection was controlled at once Emptying time determinations with the Cinex camera a few months later seemed to us to be all-important, showing, as they did, very rapid and equal physiologic expulsion of the injected medium Nevertheless, and rightly, von Lichtenberg states that one is able to interpret the dynamics of the urinary tract by observing the expulsion of uroselectan He immediately follows this statement, however, by warning that good films may be expected only when the kidney

is a sort of index to glomerular function, so that in cases with gross involvement of the renal cortex its use is unsatisfactory. So, also these drugs fail to produce satisfactory roentgenograms in those disease processes in which for any reason the eliminative activity is in abeyance. We have been disappointed almost uniformly in cases of renal tumor, renal tuberculosis, bladder carcinoma with renal damage and suspected renal or ureteral tumor, acute pyelonephritis, and prostatic obstruction with renal failure. In spite of our experience it is probable that earlier cases of tumor and tuberculosis would have shown sufficient concentration of the medium for worthwhile information, but we are of the opinion that in either disease we will always desire confirmation by means of retrograde studies when they are available, since radical surgery is necessarily involved. A very recent case, with intolerant bladder so acutely inflamed and hemorrhagic as to make recognition of the ureters and catheterization impossible, was studied with pyelognost and, later, skiodan. Carefully timed films over periods of many hours failed to show any shadows of kidney pelvis or ureters in spite of a fair urine output. A diagnosis of bilateral multiple infected infarcts, superimposed upon a severe pyelonephritis, was made, and confirmed at autopsy. Thus we see that all methods of roentgenologic study are subject to failure.

Much was promised in connection with the intravenous media especially uroselectan, as adjunct functional tests for renal activity. The reports to date have not been convincing and the chemistry involved is too arduous, although some interesting facts were brought out by investigations instituted by us at the Detroit Receiving Hospital. Our method of recovery of the drugs and determinations of their percentages of excretion in given periods will be reported later. It would seem of value to obtain the voided urine following the administration of

uroselectan especially, and, by securing samples at as regular intervals as possible, to construct a specific gravity curve as an index to elimination time. In cases of prostatic obstruction we consider all the data available concerning the upper urinary tract of great importance, and intravenous urographic routines have given valuable prognostic data merely by the success or failure to obtain good roentgenograms.

Our personal investigations in this field, with the invaluable aid of the Roentgenological Department, and Dr Jarre, especially, have brought out one point which seems to be of the greatest significance. It is that the normal individual filters the drugs used so rapidly as not to allow complete visualization of the tract lumina so that in many normal studies our findings were most imperfect. The use of the Cinex camera, with its many exposures, allows a pieced together picture, which gives fairly complete detail. This camera would provide the ideal means for all intravenous urographic studies. Our original serial roentgenographic findings with pyelognost and uroselectan have been reported before the American Urological Association and will appear in the official journal of that organization. The most brilliant and successful films have universally been those obtained in cases with good, or reasonably good, renal function on the involved side, but partial obstruction, or apparent obstruction in the ureter or at the bladder neck. Such cases are those with ureteral spasm, stricture, or calculus, often accompanying hydronephrosis, hydronephrosis itself without easily demonstrable block, prostatic obstruction in any of its forms, and urethral stricture. Many other observers have reported the same sort of successes, although it must be added that the original workers in the field, and the current advertisers, give one the impression that any and all kidney pelvis and ureters are readily visualized by their partic-

them full during the intervals between exposures. Whether this is an aid or not, we cannot state, since in our hands so many failures still occur. One German writer proposed such a method of compression, and reported it favorably some time after our own experimental use of rectal pressure was begun.

These observations, from a personal standpoint, are based upon the use of—

Pyelognost in 15 cases

Uroselectan in 83 cases

Skiodan in 25 cases

The majority of these intravenous studies have been made in the Grace Hospital, and our early practice was with the use of the Cinex camera in all cases in which good films were found possible. These included a considerable series of normal individuals, and reference has already been made to a report of our findings. Several patients have been examined by this method in several other hospitals. In a number of instances, the drug has been injected in one of our offices, the patient being sent at once to a nearby X-ray laboratory, where films were taken within fifteen minutes of the injection and at stated intervals thereafter. In addition we have had access to uroselectan and skiodan studies made by other local urologists. While there is reason to feel that best results are obtained with many repetitions in the same surroundings and with an exact technic, we believe there is some advantage in the opportunity to observe such a relatively simple procedure in several different places. One may have the co-operation, for instance, of numerous excellent roentgenologic specialists. Our injections have all been made with the gravity method.

Concerning pyelognost, it is necessary to say only that we have discontinued its use. We obtained excellent results in cases with impacted ureteral calculi and early hydro-nephrosis, but the reaction is rather horrible for the patient, and our percentage of fail-

ures was greater than with either of the later drug compounds.

Judging the more than one hundred cases in which uroselectan and skiodan have been used, we may rightfully conclude that for urinary lithiasis, pyelectasis, and ureterectasis, together with the various anomalies, intravenous urography has been gratifyingly successful, provided there has been reasonably good function as indicated by our standard colorimetric and chemical blood analyses. Braasch found the method of value for—

- 1 Identification of shadows
- 2 Determination of the intrarenal situation of shadows
- 3 Ascertaining the differential renal function
- 4 Demonstration of coincident disease or anomaly in the affected kidney
- 5 Determination of the functional capacity and disease or abnormality in the kidney

In an analysis of forty cases of renal lithiasis, we are particularly in accord with Braasch except that, for differential renal function, intravenous urography cannot be depended upon in our hands. In his series, Braasch observed two cases in which evidence of uroselectan could not be seen in the affected renal area, and in which at operation the kidneys in question were found to be normal.

In addition to our foreign urologists, several in America have stressed the importance of diagnostic data obtained with uroselectan in cases of renal tuberculosis, among these are Lowsley, of New York, and Sweetser, of Minneapolis. We have not had such good fortune, as already stated, but remain hopeful inasmuch as with this disease there are many favorable arguments against ureteral catheterization. Herbst reports a case indicating that his experiences tally with our own as far as positive urographic evidence goes. He also states that in a case

Fig 4-4 Uroselectan urogram showing large stone in the pelvis of the right kidney. This bizarre type of pelvis is well visualized, as are the ureters and the bladder.

Fig 4-B Lateral exposure showing the same pathology in the same case (Courtesy of Dr Weltman)

function is satisfactory. Only too often we need diagnostic information most when the renal activity is not satisfactory. Von Lichtenberg also points out that the mechanics of the ureter can be studied by intravenous urography, but I submit, as an apparent fact, that these physiologic notations can be made only if and when the intravenous medium concentrates sufficiently in the urinary tract lumina.

As a part of the technic for intravenous work, the early writers advised having the patient under examination void before exposures, so as to allow visualization of the lower ureters in their entirety; later workers have stated that by holding the drug-bearing urine there will be better visualization of the ureters, at least down to the bladder shadow, this being based upon the theory that the full bladder slows the excretion

from the ureter. We do not agree with this theory, nor has the practice borne fruit in our hands, although, in some cases of incontinence, failure to secure good roentgenograms was ascribed by our X-ray colleagues to this same incontinence. Other means for the compression of the lower ureteral segments have been widely advocated, principally the use of rubber bags for lower abdominal pressure. This technic has been stressed in England, and lately Herbst, in the American *Journal of Urology*, has spoken of its value. We are unconvinced of the worth of this method, and feel that it may add to the already frequently disturbing factor of flatulence which so often develops rapidly, especially after the administration of uroselectan. To attempt a more direct means of compression we have used air-distended bags in the rectum, keeping

our finding it a bit more trustworthy seems an accurate observation Skiodan, however, is cheaper, and can be kept indefinitely after it is put into solution, an older preparation of uroselectan after several sterilizations, even with proper addition of water, produces greater reaction than when freshly used. In the matter of reactions too, there is some difference, since with skiodan there is none whatever, while uroselectan usually causes pain at the site of injection and in the upper arm, along with the well-known though transient general reactions. It appears also, that skiodan filters through the kidneys somewhat more rapidly than uroselectan, a fact which may account for some of its failures with us. As yet there is not much material in the literature concerning skiodan which was informally reported as very successful at the Mayo Clinic a good many months ago. However, Ochsner and Wishard have recently emphasized the importance of taking very early films after its administration, and the manufacturers have stressed this point as of additional value for the drug.

Pyeloscopy, a valuable asset in urography, particularly in the study of pelvic and ureteral function, has been discussed by us in previous articles, it has been often referred to in the foreign literature, especially the French, and several times in our own journals in connection with excretion X-ray studies. It does not appear to fit in very well with intravenous urography, because of insufficient density of the media. We have been able in many cases to determine the most appropriate time for serial films on the Cinex camera with preliminary fluoroscopic study, but cannot get clear detail for evaluation of pelvic or ureteral outlines in most instances. This latter is so nicely possible with retrograde urography that the devotees of pyeloscopy are loath to take up the intravenous methods. With pyeloscopy

Fig. 6. Uroselectan study, 30 minutes after injection showing complete calcification of the right kidney (healed tuberculosis). The left pyelo-ureterogram and cystogram were excellent. No drug was secreted on right side.

and retrograde urographic diagnosis, the examination of the patient in both prone and erect positions has become routine. We have without valid excuse failed to practise the taking of exposures in the erect position with many intravenous studies, thereby overlooking an important step for deriving the most value possible from the film studies. It is apparent that this weakness is more or less universal, and we have seen specific instances in which, after definite conclusions had been reached in a given case, further important data were reached only after confirmative retrograde studies in the two positions. In one recent case an intravenous series failed to show much ptosis in the upright posture while a later retrograde film, similarly taken, showed not only marked

Fig 5-A Retrograde pyelogram in a double kidney which shows the lower pelvis to be pyelectatic

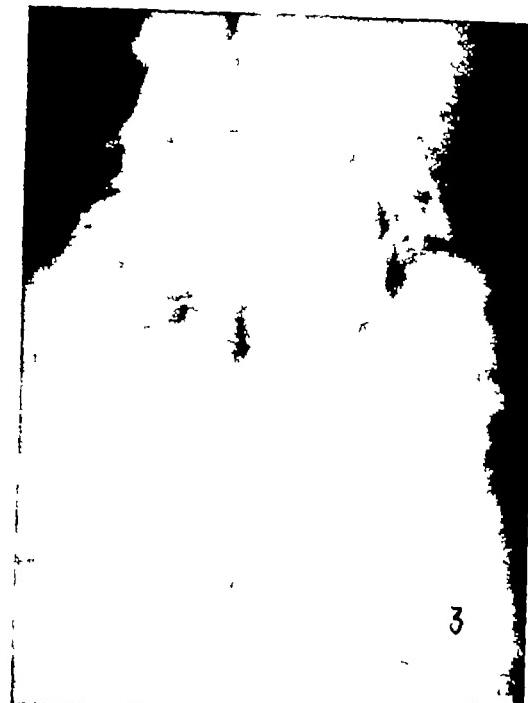

Fig 5-B Same case, uroselectan study allowing visualization of multiple calculi in the diseased pelvis. The calculi are visible in the plain films (Courtesy of Dr Plaggemeyer)

of polycystic kidney, and in tumor (renal) cases, the pelvic fillings were not sufficient to be of diagnostic value

Herbst's remarks upon the comparative value of intravenous urography (with uroselectan) are very timely, and we especially admire our former teacher, Bugbee, for his early warning against over-enthusiasm for this type of urography, which he called but a method of corroboration to supplement our proven methods of diagnosis. Viethen, in Germany, Hyman and Beer, in this country, have stressed the value of intravenous urography in children, yet we have found a high percentage of failures with both uroselectan and skiodan.

Since so much of the early work in excretion urography was done with oral administration of contrast media, referring particularly to the efforts of Rountree and his

associates, and since there are some things lacking in our present methods and preparations, it is well to bear in mind that along with the hoped-for improvement in intravenous media may come the evolution of a regularly successful drug for oral use. Several of the foreign writers have discussed this phase of the subject at some length.² Oral urography will make its appeal especially for the obscure medical cases undergoing complete study, the intravenous methods have failed rather dismally in our hands, for this type of patient, in contrast to Kidd's prediction of a year ago.

A word is in order as to the relative merits of uroselectan and skiodan. Whereas we have had more experience with the former there is so little difference in the technic and activity of the two drugs that

²See bibliography, page 52.

| Pyonephrosis, after spine fracture | - - - | 2 |
| Tabes dorsalis | - - - | 1 |
| Acute nephritis | - - - | 1 |
| Subacute pyelonephritis | - - - | 3 |
| Total | - - - | 25 |

In this series also, one notes a wide variety of disease, and may make fair deductions as to the adaptability of the medium for good contrast shadows. Thirteen cases of the 25, or 50 per cent, we have marked as failures. They include the case of ectopic kidney, which incidentally was a single congenital kidney, the cases of acute nephritis and pyelonephritis, that of tabes, which was a patient with good renal function, one case with pyonephrosis after spine fracture, two cases of prostatic hypertrophy, the case of renal tuberculosis, and one case each from the hydronephrosis and lithiasis groups.

In analyzing part of the material recorded here, a few months ago, we classified many of the instances in which intravenous studies were made as partially successful, obtaining a better set of percentages for intravenous urography. We are convinced that this was a bad precedent, and now classify all investigations as either diagnostic or failures. Naturally, in many instances, one kidney and ureter will be visualized while the other is not, but this means diagnostic information, and usually helps in placing the disease process. In this earlier analysis, we tabulated 14 cases in which retrograde study may not have been necessary prior to the institution of therapy as completely diagnosed as to roentgen-ray information. This number was much below the 50 per cent level which our larger group of cases supplies in that it represented cases culled from a total of 38. So one may assume that, by selecting cases for intravenous study, a much higher rate of successes may occur. For the

Fig. 7 Pyelogram urogram, showing excellent demonstration of the bladder and remaining kidney, after nephrectomy.

14 cases cited, a total of 41 cystoscopic procedures, operative and for therapeutic manipulations, were necessary in the periods of treatment. It is evident, therefore, that intravenous urography does not displace cystoscopy in the care of genito-urinary disease.

The habit of illustrating a paper upon our current subject with excellent roentgenograms has become general, it would seem to be a dangerous one, as the casual reader is prone to think that all intravenous urographic studies are as satisfactory. We shall err, however, along the same line, presenting some of our successful films, since the other (and larger) group is worthless, except in relation to the case represented, as negative data.

One step in urography has been neglected, especially in this country, and that is the study of urethrograms. These films, which

ptosis but also an extreme rotation of the kidney

A tabulated summary of cases subjected to examination by intravenous urography follows

| | |
|--|-----|
| Total number of cases | 123 |
| Classification, without reference to medium | |
| Normal subjects | 18 |
| Lithiasis | 19 |
| (a) Unilateral | 6 |
| (b) Bilateral | 16 |
| Pyelonephritis, subacute and chronic | 3 |
| Pyelonephritis, acute | 2 |
| Hydronephrosis, with high obstruction | 8 |
| Hydronephrosis, with involvement of ureter | 4 |
| Hydronephrosis, bilateral | 5 |
| Renal tuberculosis | 3 |
| Renal tumor | 3 |
| Carcinoma of bladder | 1 |
| Carcinoma of bladder, ascending infection | 2 |
| Reduplication of pelvis and ureters | 7 |
| Prostatic hypertrophy, with retention | 1 |
| Ectopic kidney | 2 |
| Extreme nephroptosis | 3 |
| Pyonephrosis secondary to ascending infection after spine fracture | 5 |
| Urethral stricture | 1 |
| Bilateral acute septic renal infarction | 2 |
| Acute nephritis, subsiding | 1 |
| Tabes dorsalis, with bladder symptoms | 3 |
| Cases with single kidney, congenital | 1 |
| Studies made for investigation of remaining kidney, with findings as follows | 1 |
| (a) Normal | 5 |
| (b) Infected | 1 |
| Cases following implantation of ureters | 2 |

Obviously we have included a wide variety of lesions, this, together with the normal case studies, was a deliberate attempt to determine the value of the method in routine diagnosis. In the normal subjects, the best results were obtained in those cases examined following nephrectomy (detailed reference to that series has been made in the former paper)

Next in line come the groupings which include ureteral obstructions or obstruction at the bladder neck, or in the urethra

TABULATION OF CASES WITH REFERENCE TO VARIOUS MEDIA

| | |
|--|----|
| 1 Pyelognost | 6 |
| Normal subjects | 4 |
| Lithiasis | 4 |
| Case following implantation of ureters | 1 |
| Suppurative focal nephritis | 1 |
| Cases found normal following nephrectomy | 2 |
| Infected remaining kidney | 1 |
| Total | 15 |

Of this series, the normal group proved almost universal failures. Failure also occurred in the instance of transplanted ureters, and in that of focal suppurative nephritis. Satisfactory films were obtained in one of the nephrectomy series, and three of the lithiasis series, these three being instances of impacted ureteral calculi.

| | |
|--|----|
| 2 Uroselectan | 12 |
| Normal subjects | 17 |
| Lithiasis | 4 |
| Renal tuberculosis | 2 |
| Renal tumor | 4 |
| Carcinoma of bladder | 2 |
| Reduplication of pelvis, ureters | 2 |
| Acute pyelonephritis | 5 |
| Prostatic hypertrophy | 5 |
| Hydronephrosis | 9 |
| Urethral stricture | 5 |
| Pyonephrosis after spine fracture | 1 |
| Acute suppurative nephritis | 1 |
| Subacute and chronic pyelonephritis | 13 |
| Tabes dorsalis | 2 |
| Cases with single kidney | 3 |
| Case following implantation of ureters | 1 |
| Total | 83 |

Omitting the twelve cases which were normal subjects, and one of the cases having reduplication of pelvis and ureters, but no pathology, we have a total of 70 cases with disease in the urinary tract, of these, 29, or approximately 50 per cent, did not give films that might be called diagnostic. The groups in which failures were most common include all cases of renal tuberculosis and renal tumor, a large proportion of the pyelonephritis series, and pyonephrosis, both when secondary to spine fracture with ascending infection, and associated with prostatic obstruction and stricture of the urethra. One note the largest series as that of lithiasis, and here we found our best results, the high percentages being in cases with ureteral or small pelvic calculi. Another large group is that of hydronephrosis, and here also we found good results, with the best in the presence of definite ureteral pathology. The cases with low obstruction also gave good visualization when renal function was well preserved.

are simple in execution, are important in both pre-operative and post-operative phases of bladder neck and urethral obstructive lesions, important, too, in the recognition of diverticula in both sexes. The British urologists have stressed urethrograms, and Young's clinic, in Baltimore, has obtained valuable data by their use.

SUMMARY

The experience represented by 123 consecutive intravenous urographic studies has been recorded in sufficient detail to indicate the value in a new method of diagnosis. Certain types of renal disease have been shown as promising little or no diagnostic evidence after the administration of any of the contrast media now employed. Of these we may mention particularly renal tuberculosis, renal tumor, acute inflammation, and marked renal insufficiency as portrayed by advanced pyonephrosis, septic renal infarction, and advanced prostatism.

Present-day conceptions of the general practitioners in the medical profession include a tendency to over-enthusiasm for intravenous urography, which is not shared by a large group of urologists. It is apparent that this method of diagnosis should not be practised by urologists and roentgenologists independently, and that general laboratories are to be condemned for attempting to place lesions of the genito-urinary tract by means of intravenous urography.

Before uroselectan was available, we used pyelognost in our practice, later continuing, to compare it with the former. More recently we have used skiodan. Of these three preparations we find uroselectan the most satisfactory, and plan to confine ourselves to that drug (now called "Iopax"). It must be admitted that skiodan is better tolerated, but, as has been reported by so many others, and lately ourselves, uroselectan is apparently quite safe. With all three

drugs we have seen temporarily alarming reactions.

NEW RADIUM IN CANADA WILL BREAK WORLD MONOPOLY

That radium to the value of hundreds of millions of dollars, just discovered in Canada, will break the Belgian world monopoly of this precious substance and speed up the relief of cancer victims is the opinion of competent mining experts in Washington

The pitchblende treasure bearing \$150 worth of radium in every pound of ore, discovered by Gilbert Labine and Shirley R Cragg, airplane prospectors, at Labine Point in the Great Bear Lake region, is equal in richness to the best ores of the Belgian Congo, which since 1922 have driven all competitors, including the United States, from the market

The new ore is here described by geologists as "a very substantial deposit of high grade material" yielding 3 to 4 grams of

radium per ton Twenty tons have already been shipped on a fur steamer of the Mackenzie River, and forty more tons have been mined and are ready for shipment, at a cost which compares favorably with Belgian freight charges on the long passage from Africa to the refineries in Europe

Hundred-pound lumps were actually picked up on the surface The radium from these will yield \$70,000 a gram, whereas the most valuable emeralds fetch only \$5,000 a gram Silver ore yielding \$300 a ton has been found alongside

The Canadian discovery, consisting apparently of several thousand tons of ore, will add greatly to the world's present 600-gram total supply of radium Treatment of cancer, until now hindered by the prohibitive prices, will be greatly helped — *Science Service*

AS NEPHROPTOSIS AND URINARY STASIS

upper third of the lumbar fossa, a space which is bounded behind by the muscles of the loin and back, in front by the peritoneum, above by the diaphragm, and below

peritoneum, and the right kidney lies a finger's breadth lower than the left said to be due to the fossa on the right being less capacious on account of the

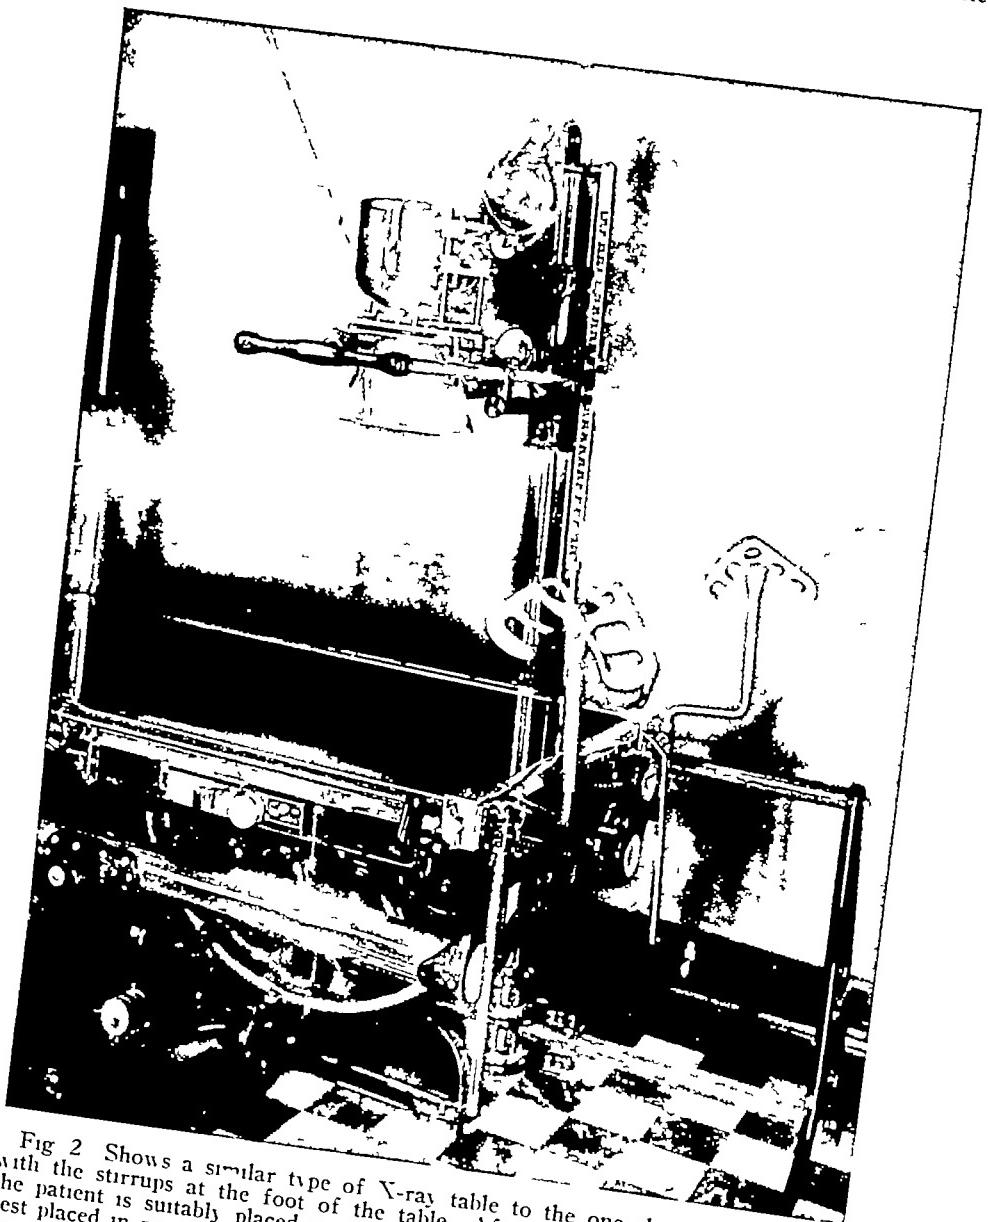

Fig 2 Shows a similar type of X-ray table to the one shown in Figure 1 with the stirrups at the foot of the table. After the cystoscopy is completed the patient is suitably placed on the table, the stirrups removed, and the foot rest placed in position. Pyeloscopy and pyelography are then carried out in the usual position.

by the ilium. The kidney extends from the upper margin of the twelfth rib to the lower margin of the second lumbar vertebra. The kidneys are situated entirely behind the

ence of the liver and an inclination of the vertebral bodies to that side.

The peritoneal relations are somewhat different on the two sides. On the right side

THE DEMONSTRATION AND SIGNIFICANCE OF NEPHROPTOSIS AND URINARY STASIS

By HAROLD L MORRIS, M D, F A C S, DETROIT

IN the study of urinary stasis of the upper urinary tract, one must be familiar with the normal anatomic relationship of the kidneys and other organs, as well as the supporting structures of the kidneys.

The recognition of nephroptosis, and the various forms of treatment for the same, is as old or older than urology itself, however, the roentgen-ray demonstration of nephroptosis is a more recent development.

It is the purpose of this thesis to again call attention to the anatomic relationship

of the kidneys and other organs, as well as the supporting structures of the kidneys, the histologic structure of the renal pelvis and ureter, also the physiologic action of the renal pelvis and ureter. As there may or may not be a stasis of urine in the renal pelvis, as a result of nephroptosis, a method is proposed for determining this factor which should be carried out in cases in which investigation of the higher urinary tract is indicated.

As shown by Southam (1), the kidneys lie in the lumbar region on either side of the vertebral column. Each kidney occupies the

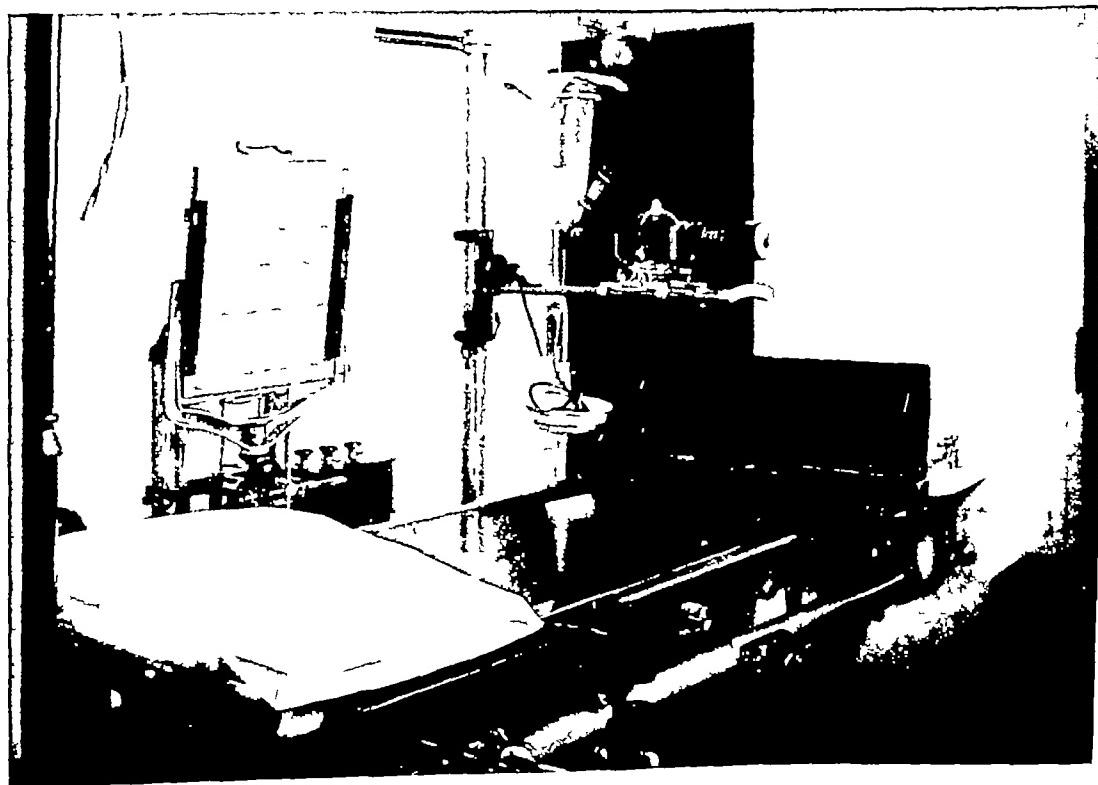

Fig 1. A motor-driven, tilt X-ray table, with a suitable drum installed at the foot of the table for cystoscopy to be performed with the patient in the prone position, legs extended. The Bucky moves the full length of the table, the tube stand, which is attached to and moves with the table, locks in position over the center of the Bucky. The fluoroscopic screen has underneath two slots for carrying a 10×12 cassette so that films may be made during the course of fluoroscopy, using the fluoroscopic tube for making the exposure.

has the appearance of a cone with the apex above, while in the male it is more cylindrical in shape and tends to become narrower below. This is due to the increased breadth of the female pelvis, and in some cases an acquired narrowness of the lower costal margin. In the male, the lower ribs are more horizontal and the chest has a greater width, while the measurement across the iliac crest is relatively small. In the female, the intercostal diameter of the body may be greater than the transverse diameter of the lower thorax by two and one-half centimeters. In males, the fossæ are distinctly pear-shaped and become narrower below, while in females they are relatively narrow above and broaden out below or are cylindrical in shape. Further, a comparison of the fossæ on opposite sides of the body shows the right recess is usually a little larger than that on the left side.

In most cases the fossa of the right side is more capacious than that on the left. Southam demonstrated this fact by making transverse sections of the casts, cut with a band-saw at the level of the first lumbar vertebra. In the male, the right recess was thus shown to be appreciably larger than the left, the average measurement in the right side being about two centimeters broader than the left at the level of the first lumbar vertebra. The fossa of the right side is deeper than that of the opposite side at the same level by one centimeter.

The upper end of the kidney is rather greater than the lower in circumference, more curved, and nearer to the vertebral column. It corresponds to the intervertebral disc between the eleventh and twelfth thoracic vertebrae. The lower end is bounded by the intervertebral disc between the second and third lumbar vertebrae.

The fixation of the kidney depends on two factors: first, the fatty capsule through which runs connective tissue fibers from the fibrous capsule to Gerota's capsule; second, Gerota's capsule. This is the fascial envelope

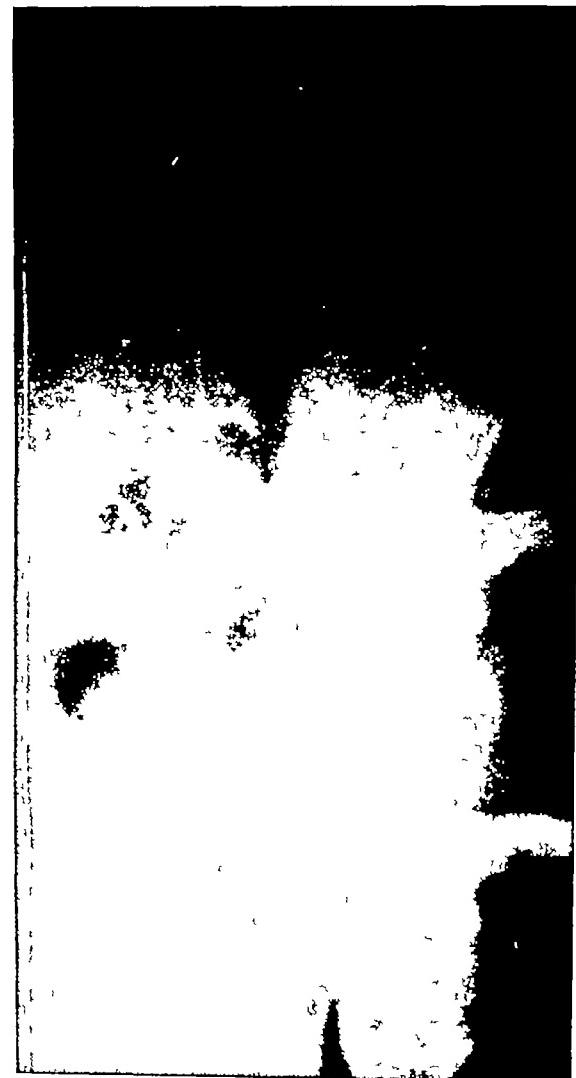

Fig. 4 The catheter in this film has been withdrawn into the upper ureter and the point of narrowing is very readily seen at the ureteropelvic sphincter.

Had a catheter been inserted no farther than this and injection of pyelographic medium begun, one of two things would have happened: either the fluid would have returned alongside the catheter, or, if the catheter was of sufficient caliber to occlude the ureter, then dilatation of the ureteropelvic sphincter would have resulted in rather marked renal discomfort and spasm.

Films reproduced in Figures 3-B and 4 were made with the fluoroscopic tube, having the cassette on the anterior surface of the body without the Bucky diaphragm.

which surrounds the kidney, and is quite distinct from the fibrous capsule of the kidney which closely invests the organ and lines the renal sinus. This is sometimes also called the *fascia renalis*, *fascia propria*,

Fig 3-B After the renal pelvis is well visualized fluoroscopically the catheter is withdrawn to just outside the ureteropelvic sphincter and films are made with the fluoroscopic tube, without the Bucky diaphragm. In almost all instances a much clearer outline of the pelvis is thus obtained for permanent records than with the usual procedure on a larger film with the Bucky.

the peritoneum passes from the liver to the anterior surface of the kidney, the lower third of the kidney is not covered by peritoneum. The area of the left kidney covered by the peritoneum is far less than that of the right kidney.

The upper third of the left kidney is related to the stomach, while the pancreas crosses its middle third, the lower third is covered by peritoneum and related to coils of small gut, the outer border being related to the spleen above and the colon below.

The upper two-thirds of the right kidney is covered by the under surface of the liver, the lower third by the hepatic flexure of the colon. The inner border is related to the duodenum.

Fig 3-A The tip of the ureteral catheter in correct position within the renal pelvis. With catheter thus placed, slow injection of pyelographic medium results in no spasm of discomfort to the patient, neither is there an over-distention, with resultant spasm, whereas, the entire filling is readily seen fluoroscopically.

The posterior surfaces of the ascending and descending colon are not covered by peritoneum, and hence the gut comes into relation with the perirenal fascia. The suprarenal gland rests upon the upper pole of the kidney, while posteriorly the kidney lies upon the quadratus lumborum and psoas muscles, the diaphragm, and the transversalis aponeurosis.

If the lumbar regions be examined from behind, it will be seen there is a difference in outline in the two sexes. In the female, the lumbar region broadens out below and

the vertebrae in front of the origin of the psoas muscle. The anterior layer merges with connective tissue elements at the root of the mesentery and around the great vessels. This layer does not extend beyond that point.

already described. At the level of the hilum they are kept apart by the renal vessels, while below, the ureter lies between them as it passes down to the pelvis.

At the outer border of the kidney, the

Figs 7 and 8. Bilateral pyelo-ureterograms in the prone and vertical postures, showing a rather decided loop in the upper ureter in the upright posture, and quite a decided angulation in a similar position in the prone posture.

These deformities in the ureteral outline were found to be due to an aberrant artery to the lower pole of the kidney.

In this case there is a very definite renal stasis and interference of emptying of the renal pelvis, especially in the upright posture.

to cross the midline to the opposite side. Above the hilum these two layers come together at the inner border of the kidney, being separated only by a deposit of fat, the posterior layer then becomes attached to the spinal column and the anterior ends as

two layers of fascia come together and join each other, forming a well marked band which passes out behind the peritoneum to join with the transversalis fascia. It forms an important means of fixation of the kidney. Other accounts of the arrangement of the

tunica fibrosa, capsule of Kustner or Zuckerkandl and consists of a thin sheath of fascia which completely surrounds the kidney and suprarenal body. The sheath is separated from the kidney by a layer of fat

lies between the peritoneum and the anterior surface of the kidney. Where it comes into relation with the peritoneum the two layers are closely blended together, where, however, the peritoneum is absent, it is related

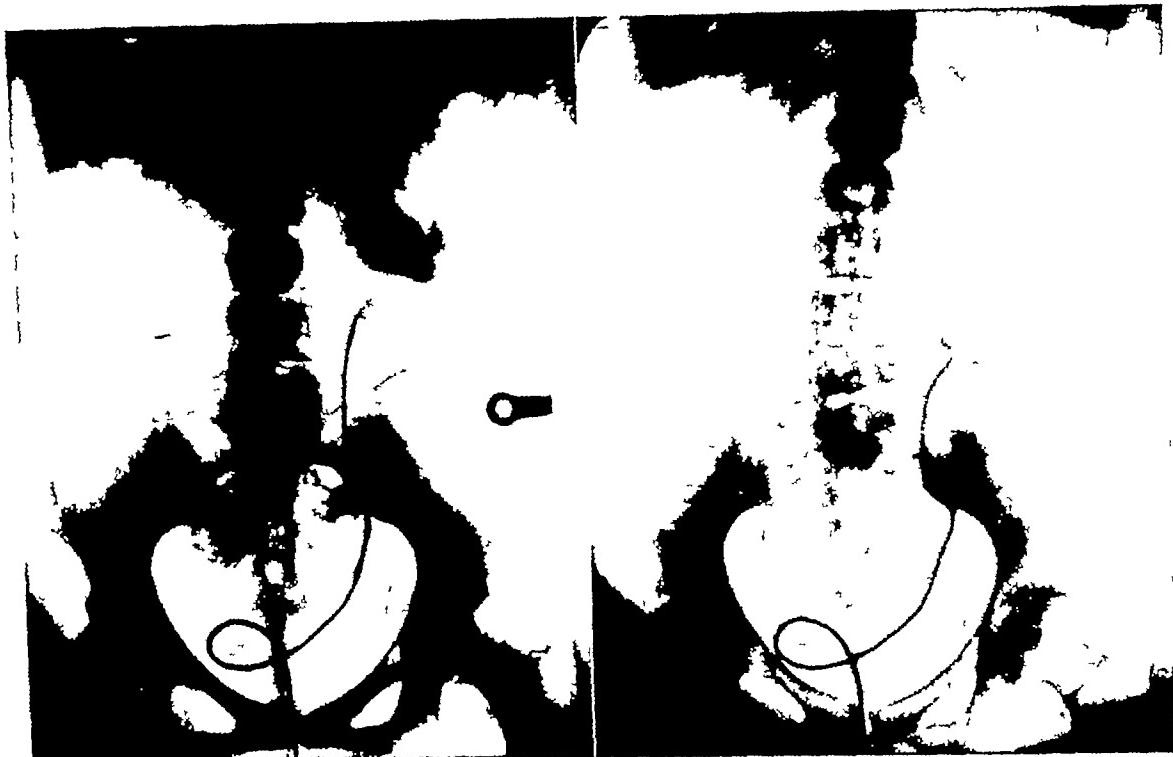

Figs 5 and 6 Pyelo-ureterograms in the prone and vertical positions

the ureter just below the ureteropelvic junction
In the vertical posture, however, this was not sufficient to interfere with nor-
mal emptying of the renal pelvis while the patient was standing

within which the kidney is embedded and consists of two layers, an anterior and a posterior layer

The anterior perirenal layer, or fascia of Toldt, is a thin, fibrous membrane which

to the neighboring viscera the posterior layer or fascia overlying the lumbar muscles At the inner border of the kidney this layer reaches to the vertebral column and becomes firmly attached to the bodies of

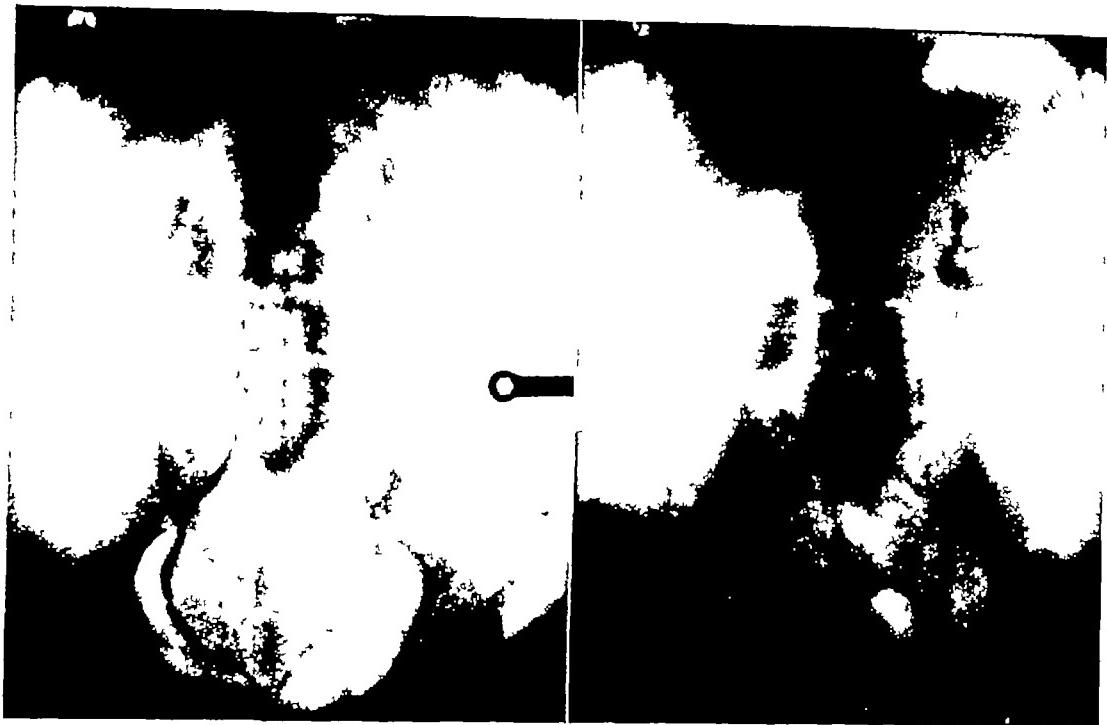

Figs 11 and 12 Left pyelograms in the prone and vertical positions showing a large hydronephrosis, the hydronephrotic sack not being clearly outlined in these films. However, there was a very decided retention, with little or no infection. At operation an aberrant vessel was found in the lower pole of the kidney, after this was severed, the renal pelvis readily emptied.

that showed that in the female the kidney has a greater range of movement, this has been considered as due to the shape of the renal fossa in this sex. On deep inspiration and expiration the renal pelvis rises or falls to the same extent as the diaphragm. In patients with enteroptosis the amount of displacement is increased and the degree of nephroptosis is readily detected. The right kidney moves more freely than the left, probably because the movements of the diaphragm are more directly transmitted to it through the liver, which descends into the renal pouch with each inspiration.

The movable kidney may be described as one which moves with abnormal freedom behind the peritoneum. The earliest reference in medical literature on the subject of movable kidney is found in the writings of Meuse, of Venice, who wrote a chapter on this subject in 1497, of Francis Pedemontanus, in 1581, and of Riolan, in 1682. Rio-

lan observed that the normal condition of the kidney is a fixed one in the flank, but that under certain conditions it becomes movable, and that stones or growths in the kidney especially favor the loosening. Rayner, in 1846, in his work "Diseases of the Kidney," reported seven cases of mobile kidney, which he thoroughly studied, not only from the anatomic but from the clinical standpoints of diagnosis, symptomatology, and treatment. He noted that the conditions were commoner in females than in males, and that it affected more frequently the right kidney. He also noted that pregnancy and heavy lifting were contributory causes, and that patients were usually thin and hypochondriac. Finally he stated that in some cases bandages gave relief. In 1864, Dietl described the crises found in certain cases of mobile kidney and gave to the literature the term "Dietl's crisis."

The first operation performed for mov-

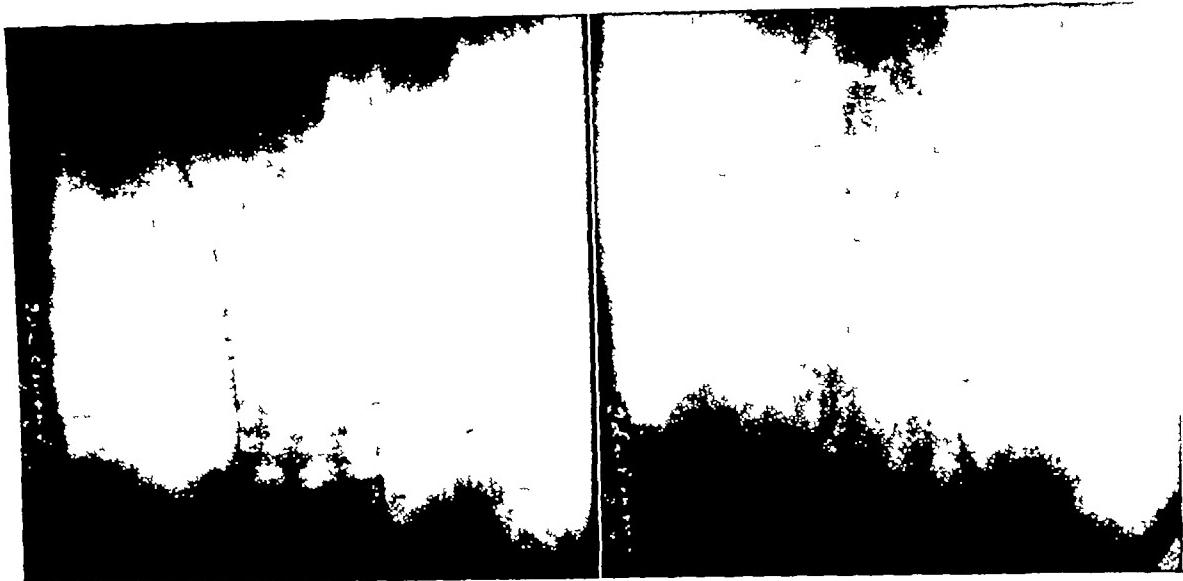

Figs 9 and 10 Bilateral pyclo-ureterograms, prone and vertical positions, revealing a very decided retention in the right renal pelvis, accompanied by infection. At operation an aberrant vessel was found in the lower pole of the kidney, crossing the ureter in its upper third in such a way that, after the vessel was severed, the pelvis readily emptied.

fascia at the outer border of the kidney are singularly incomplete. Cunningham states that the walls of the sheath come in contact and are connected with the retroperitoneal tissue. Thomson Walker merely states that the perirenal fascia appears between the transversalis fascia and the peritoneum and divides into two layers, while Kelly and Burnham find the two layers unite at varying distances and then pass forward under the peritoneum. Sir Henry Morris says it ends indistinguishably in the subperitoneal fascia, and Poirier states that the fascia is closed at the outer side, mentioning no specific attachments.

The anterior and posterior layers, after enclosing the kidney and suprarenal body in one compartment, join together at the upper pole of the suprarenal and pass up as a single strong band to unite with the tendinous area of the diaphragm. There is thus formed a strong suspensory band for the kidney when

the body is in the erect posture. The suprarenal is attached to the upper pole of the kidney by fibrous strands. The third support of the kidneys is the pressure exerted by the abdominal viscera, the fourth, the muscular tone and development of the abdominal walls, fifth, the nephrocolic ligament, and sixth, the kidney pedicle. The accessory factors such as the phrenocolic, hepatorenal, the duodenorenal ligaments, as well as adhesions between the spleen and kidney, deserve mention. The kidney normally moves during respiration, rising and falling with the action of the diaphragm. Earlier writers thought the kidney was a fixed organ, but Glenard, in 1899, showed that the organ moves with respiration. Kelly and Burnham state that the normal up-and-down movement during respiration varies from one to five centimeters, Thomson Walker observes the excursion varies from one-half to one and one-half inches. Rosen-

Figs 15 and 16 Bilateral pyelograms in the prone and vertical postures, made with the fluoroscopic tube on 10×12 films, without the Bucky diaphragm, which gave a clear visualization of the higher urinary tract. These can easily be made during the course of fluoroscopic study. Although there is a pronounced right renal ptosis in this instance, the pelvis was found to empty normally, there being no stasis or infection. This type of case is greatly relieved by the wearing of an abdominal support.

up to a comparatively recent date, the diagnosis depended largely on palpation and percussion, X-ray examination of the gastrointestinal tract, and observations of various surgeons when operating within the peritoneum. As a result a long list of symptoms as well as diseases has been attributed to ptosed kidneys, with resultant urinary stasis.

Bailey (2) states "The kidney pelvis, with its subdivisions, the calices and the ureter, constitutes the main excretory duct of the kidney. Their wall consists of three coats—an inner mucous, a middle muscular, and an outer fibrous."

The mucosa is lined by epithelium of the transitional type. There are from four to eight layers of cells, the cell outlines are usually well defined, and the surface cells, instead of being distinctly squamous, are only slightly flattened. Less commonly, large, flat, plate-like cells, each containing several nuclei, are present. Diffuse lymphatic tissue frequently occurs in the stroma especially of the pelvis. Occasionally the lymphatic tissue takes the form of small

nodules. Mucous tissue takes the form of small nodules. Mucous glands in small numbers are found in the stroma of the pelvis and upper part of the ureter. There is no distinct submucosa, although the outer part of the stroma is sometimes referred to as such.

The muscularis consists of an inner longitudinal and an outer circular layer. In the lower part of the ureter a discontinuous outer longitudinal layer is added.

The fibrosa consists of loosely arranged connective tissue, containing many large blood vessels. It is not sharply limited externally, but blends with the connective tissue of surrounding structures, serving to attach the ureter to the latter.

The larger blood vessels run in the fibrous coat. From these, branches pierce the muscle layer, give rise to a capillary network among the muscle cells, and then pass to the mucosa, in the stroma of which they break up into a rich network of capillaries. The veins follow the arteries.

The lymphatics follow the blood vessels,

Figs 13 and 14. Bilateral pyelo-ureterograms in the prone and vertical positions showing bilateral pelvic stasis and at operation an aberrant vessel in the lower pole of each kidney was found. This is the only situation I have observed in which aberrant lower polar vessels were bilateral.

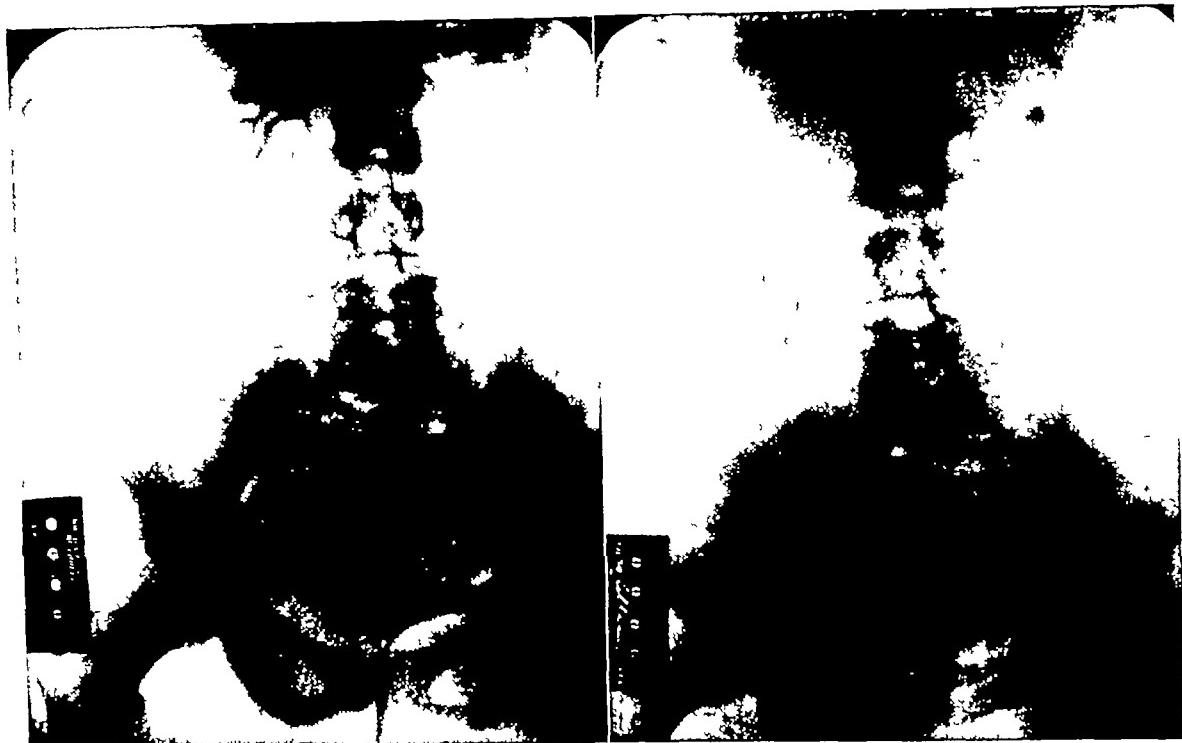

able kidney was by Martin, of Berlin, in 1878, when he carried out nephrectomy in two cases. Suspension of the organ was first carried out by Hahn, of Berlin, in 1881. His lead has been followed by many operators, and a vast number of operations have been devised to secure fixation of the kidney. Glenard, in his writings in 1885 and 1900 maintained that movable kidney was not a condition in itself, but part of a general enteroptosis, due to congenital weakness of the supporting structures of the abdominal viscera. Landau, in 1881, had maintained that the kidney was normally fixed and any degree of mobility was abnormal. This we now know is not true, as the organ moves with respiration.

More recently Fita, Dell, Treves, Goelet, Suckling Billington, Newman, Edebohls,

and Lane have added to the literature on this subject, while Sir Henry Morris and Sir William Roberts have contributed valuable additions to our knowledge. Up to 1901, Sir Henry Morris had performed 98 nephropexies with one fatal result.

Sappey and Zuckerkandl, in 1883, described a thickening of the connective tissue on the posterior surface of the fat capsule of the kidney, which he called the fascia retrorenal. Gerota, in 1895, described a layer on the anterior surface, which he called the fascia perirenal. The fascia is more marked on the left side, and this fact was first demonstrated by Toldt. Apart from this, little original work on the fascial attachments of the kidney appears to have been done.

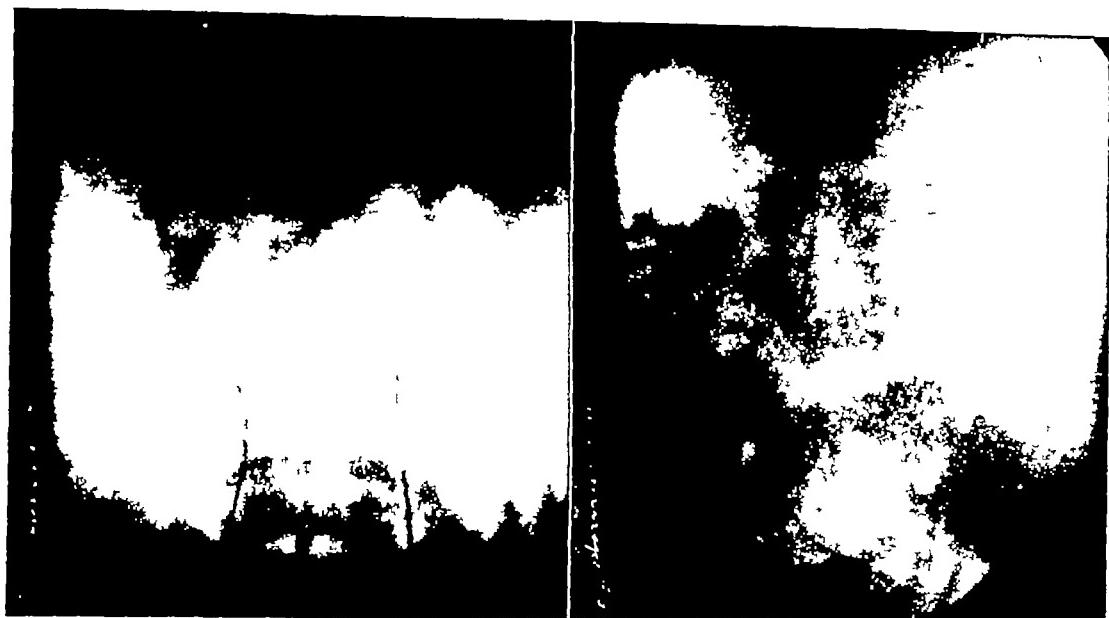

In all writings on motility of the kidney

Figs 19 and 20 Right pyelo-ureterogram in the prone and vertical postures reveals a normal appearing ureter and renal pelvis in the prone position, however, in the vertical position there is a very decided ptosis. This situation is one frequently encountered in patients who have persistent right abdominal discomfort, for which many have a "chronic appendix" removed.

Figs 21 and 22 Left pyelo-ureterogram showing a rather decided dilatation of the renal pelvis and irregularity of the minor and major calices, suggestive of acid-fast infection. However, there is no abdominal ptosis and the ureteropelvic sphincter and upper ureter show nothing to account for the pelvic dilatation.

Figs 17 and 18. Bilateral pyelo-ureterograms made with the fluoroscopic tube, without the Bucky diaphragm, in the prone and vertical postures, showing a bilateral ptosis with bilateral stasis and bilateral pyelitis.

In this case, as well as the preceding one, with the patient in the vertical posture, the palpating hand on the abdomen could easily replace these kidneys to normal position while being observed fluoroscopically, however, without this aid there was definite stasis present.

being especially numerous in the stroma of the mucosa

Nerves—Plexuses of both medullated and non-medullated fibers occur in the walls of the ureter and pelvis. The non-medullated fibers pass mainly to the cells of the muscularis. Medullated fibers enter the mucosa when they lose their medullary sheaths. Terminals of these fibers have been traced to the lining epithelium.

Bearing in mind the histologic and anatomic data, it is much easier to consider the subject of pyeloscopy because by this procedure we actually see the motion and physiologic phenomenon of the emptying of the renal pelvis and are brought to realize that the normal renal pelvis and ureter undergo very definite rhythmic contractions and dilatations, whereas many variations are encountered and observed in the abnormal.

It really is surprising how little has been written and how little description given of the physiologic action of the renal pelvis.

and ureter, even though the anatomic and histologic structure is well known. As an example of the text-book teaching, Stewart (3) states the following "Trickling along the collecting tubules, the urine reaches the pelvis of the kidney, from which it is propelled along the ureters by peristaltic contractions of their walls and drops from their valve-like orifices into the bladder."

Muschat (4) presents data which demonstrate rhythmic contraction of the spiral muscle of the renal papilla. It seems highly probable that this muscle causes an act of suction on the papillary duct, which milks the renal papilla. The force of the contraction varies for each preparation, but the time relation for contraction remains the same about every thirty seconds.

Young (5) says "The urine passes along through the ureter from the kidney as the result of peristaltic waves which originate in the musculature of the pelvis, and extend to the ureterovesical orifice."

Fig 26 Right pyelo-ureterogram made during the latter months of pregnancy because of severe, persistent hematuria

Fig 27 The patient shown in Figure 26 refused surgical interference and two years later returned for observation and this megaloureter was seen fluoroscopically to fill. However, pyelographic medium could not be introduced into the renal pelvis

at intervals varying from six to twenty seconds

"The renal pelvis and the uppermost part of the ureter show contractions of another type, namely, small oscillations which recur much more frequently than the larger contractions

"Chloroform and ether affect profoundly the large contractions of the ureter, so as even to abolish them completely, while the smaller oscillations show a greater resistance towards anesthetics"

The clinical value and practical application of the physiologic function and activities of the renal pelvis have been called to our attention by two clinicians, one a roentgenologist in this country, Manges, and the other a urologist in Paris Legueu

The fluoroscopic visualization of the higher urinary tract is now a practical procedure. The roentgenologist of to-day not only reports the findings as protracted by the pyelograms of the renal pelvis and ureter, but he also includes his fluoroscopic observa-

tion as he does a study of the gastro-intestinal tract

We are indebted to Manges (8) for demonstrating and calling to our attention the advantages of pyeloscopy combined with pyelography, and to him credit should be given for having coined the term "pyeloscopy," for, as he states "Pyeloscopy is but a preliminary to pyelography, and adds distinctly to the comfort of the patient, as well as the safety and the accuracy of the entire procedure." Seventeen years later, he added "That is just as apt and fair a statement of reason for advocating the method to-day as it was then." Pyeloscopy, then, is indicated in every, and not only in the exceptional or selected, case.

In 1911, Manges (9) began to study the urinary tract by means of pyeloscopy as an aid to pyelography, and to date has never allowed the making of pyelographic films

Fig. 23 Right pyelogram made during the later months of pregnancy, showing a marked dilatation of the upper one-half of the ureter and renal pelvis

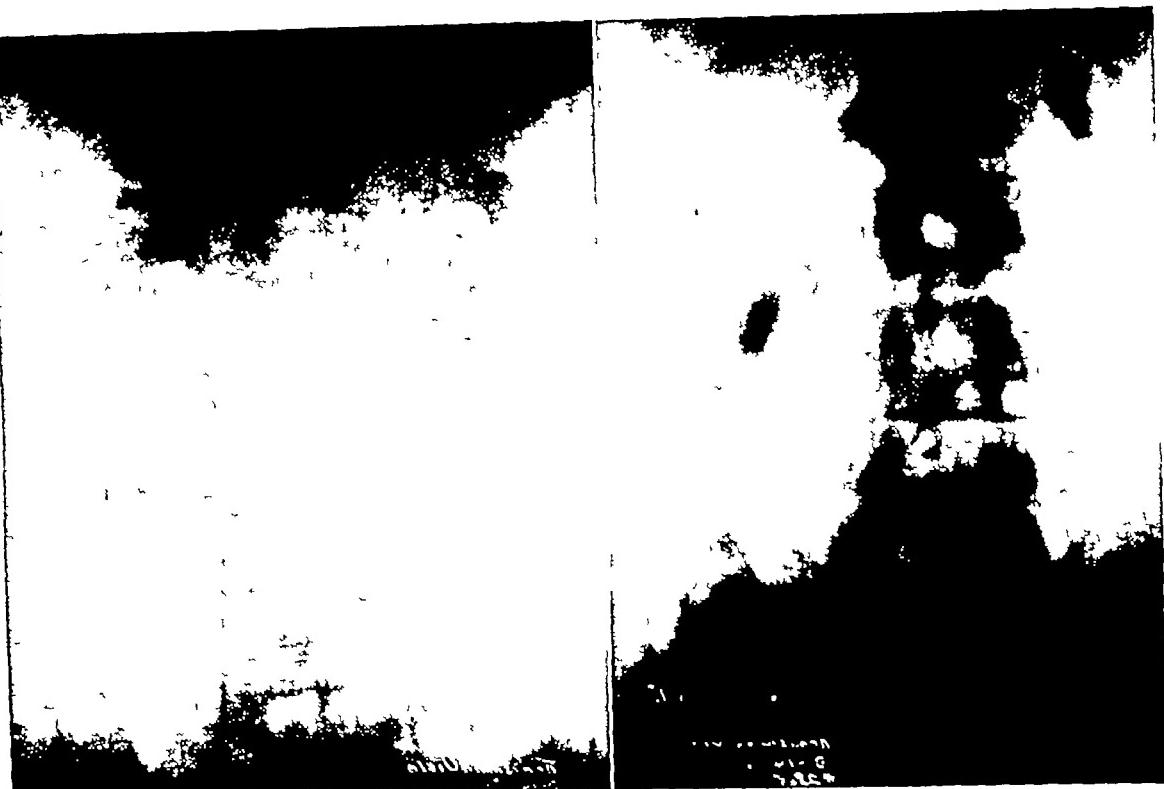

Our present knowledge of the movements of the ureter dates back to the classic studies of Engelmann (6), published about sixty-two years ago. His careful studies were made by simple ocular observation of the movements of the ureter in the dog, cat, rabbit, and rat. Engelmann made the statement that in the dog the movements might be studied by the graphic method, he, however, did not carry out such experiments.

Lucas made a rather exhaustive study of the physiology and pharmacology of the ureter in the dog by the graphic method. The essential points of his study of the ureter of dogs by the graphic method, he summarized as follows:

"Even under morphin anesthesia the middle part of the ureter (comprising at least two-thirds) shows comparatively large contractions which recur, if the urine is permitted to flow unimpeded into the bladder

Figs. 24 and 25 Right pyelogram of the same patient as shown in Figure 23, made 7 months after delivery, showing some dilatation in the upper third of the ureter and some dilatation of the renal pelvis. The upright posture shows a very marked ptosis. This is a very common finding in puerperal pyelitis.

Figs 30 and 31. Bilateral pyelo-ureterograms in the prone and vertical postures show a rather decided right renal ptosis. Fluoroscopy revealed a definite stasis.

This girl has had several major abdominal operations, none of which has relieved the right abdominal discomfort. An abdominal support was worn for some time without relief, and nephropexy was advised.

ing a five-inch film band for a unilateral study and a ten- to twelve-inch film band for a bilateral study.

As stated by Jarre (12), "The purpose of this presentation is to stimulate interest in those physiologic problems which concern medical roentgenology, with the expectation that we may derive therefrom a better conception of organic and functional normalcy and disease, and thus may improve roentgenologic diagnosis."

"Two groups of phenomena lend themselves to physiologic roentgenologic investigation (1) Those of motion which can be rendered radiovisible, and (2) phenomena of concentration and secretion of opaque substance as they are classically demonstrated by cholecystography."

"Whenever a tubular viscous is rendered radiovisible, one should study its function as well as its anatomic structure, since the eval-

uation of its physiologic behavior must be considered as equally important as—possibly even superior to—anatomic information. The omission of such observation will be regarded as negligence in medical practice of the future."

Having considered somewhat at length the anatomy, histology, and physiology of the upper urinary tract, one can now proceed with the factors pertaining to renal or ureteral stasis and the means of diagnosis at hand.

The first requisite is suitable equipment for roentgenologic study, and the table (13) which I have found most satisfactory is a motor-driven, tilt table, with the Bucky travelling the full length of the table and the fluoroscopic screen movable over the upper two-thirds.

Cystoscopy and ureteral catheterization may be carried out on the X-ray table, or

Figs 28 and 29 Bilateral pyelo-ureterograms in the prone and vertical postures showed a bifurcation of the right ureter with two pelvis on the right side.

There is some dilatation and definite clubbing of the minor calices of all three pelvis in the prone position, however, in the vertical posture, the minor calices in the superior pelvis on the right side, which were before very much blunted, are now normally cupped.

without fluoroscopic control and study as the injection is being made into the ureter or renal pelvis

If one is to determine the degree and amount of renal stasis, this can be satisfactorily accomplished only by the aid of the fluoroscope before making pyelo-ureterograms. The interpretation, therefore, largely rests with the roentgenologist and from his reports, plus the clinical evidence and the urologic findings, the urologist is able to draw a much more satisfactory conclusion with regard to treatment and further procedure.

In spite of the fact that pyeloscopy has been practised by Manges for the past twenty years, and his technic described in various journals, the roentgenologist has been slow to provide adequate equipment to carry out this procedure, with the result that pyeloscopy is made very little use of in this country.

In the past three years, the urologist has had the advantages of pyeloscopy most forcibly brought to his attention by the work of Legueu (10) in whose monograph the physiologic action of the renal pelvis and ureter is very strikingly presented. All of this one can easily see for himself, when fluoroscopic studies are made of the renal pelvis. Once having visualized the higher urinary tract, one would never be satisfied to continue the old method—working in the dark and not knowing where the ureteral catheters were, the presence or absence of stone, when the renal pelvis has enough solution for good films without over-distention of the pelvis, and resultant pain to the patient.

The very recent, original, and valuable contribution of Jarre and Cumming (11) has added to our knowledge immensely. Their appreciation of motor function and physiologic action of the renal pelvis and ureter was recorded by a Cinex camera, us-

ing a five-inch film band for a unilateral study and a ten- to twelve-inch film band for a bilateral study.

As stated by Jarre (12), "The purpose of this presentation is to stimulate interest in those physiologic problems which concern medical roentgenology, with the expectation that we may derive therefrom a better conception of organic and functional normalcy and disease, and thus may improve roentgenologic diagnosis."

"Two groups of phenomena lend themselves to physiologic roentgenologic investigation (1) Those of motion which can be rendered radiovisible, and (2) phenomena of concentration and secretion of opaque substance as they are classically demonstrated by cholecystography."

"Whenever a tubular viscous is rendered radiovisible, one should study its function as well as its anatomic structure, since the eval-

uation of its physiologic behavior must be considered as equally important as—possibly even superior to—anatomic information. The omission of such observation will be regarded as negligence in medical practice of the future."

Having considered somewhat at length the anatomy, histology, and physiology of the upper urinary tract, one can now proceed with the factors pertaining to renal or ureteral stasis and the means of diagnosis at hand.

The first requisite is suitable equipment for roentgenologic study, and the table (13) which I have found most satisfactory is a motor-driven, tilt table, with the Bucky travelling the full length of the table and the fluoroscopic screen movable over the upper two-thirds.

Cystoscopy and ureteral catheterization may be carried out on the X-ray table, or

the patient may be cystoscoped and then placed upon the X-ray table. With the Bucky at the foot of the table, the fluoroscopic screen is brought into place over the abdomen, the ureteral catheters located and note made of their position, relation to opaque bodies such as calculi, and the relative position in the renal pelvis.

The medium used heretofore for visualization of the renal pelvis and ureters has been sodium iodide 12 per cent, 20 per cent, or 30 per cent. However, as this solution is more or less irritating to certain individuals recently, use has been made of uroselectan or skiodan for injecting into the renal pelvis. These are practically non-irritating to the mucosa of the renal pelvis, ureter and bladder. Then 0.5 cc. of solution is injected through the catheter, this amount being sufficient to locate the tip of the catheter and its relation to the renal pelvis, whether it is below the ureteropelvic sphincter, within the pelvis proper, or in one of the major calices. Severe pain may follow the injection of a greater amount of fluid if the catheter tip is below the ureteropelvic sphincter or if the tip of the catheter is within one of the major calices and a sudden over-distention of that particular calyx takes place.

Often the entire renal pelvis is clearly outlined, especially if one of the more concentrated solutions is used, upon the injection of only 0.5 cubic centimeter. Up to this time there has been no pelvic spasm with resultant discomfort. After the initial injection of one-half cc., 1 cc. at a time is added until the entire pelvis is clearly outlined. At this time 10×12 films are made, using the fluoroscopic tube and placing the cassette under the fluoroscopic screen in the holder designed for this purpose, without a Bucky diaphragm. As a rule a more clear-cut image of the pelvis is thus obtained than when 14×17 films of the entire genito-urinary tract are taken with the Bucky.

During this part of the examination the degree of respiratory excursion of the kid-

ney is noted and the patient is then placed in the erect posture and the actual amount of excursion from the prone to the vertical position is observed.

It will be noted that many renal pelvis readily empty even though there is an abnormal amount of motility with resultant tortuosity of the ureter. In the erect posture, should there be a delay in the emptying of the renal pelvis, by means of counter-pressure with the hand of the operator on the abdomen the kidney can easily be elevated and then one sees the normal process of emptying continued.

In another instance there may be little or no appreciable excursion of the kidney, and yet in the erect posture there is a delay in emptying. This may be due to fixation of the upper ureter and even so little downward descent of the kidney is ample to prevent normal emptying with resultant stasis of varying degrees.

I am of the opinion that the respiratory excursion of the kidney in the prone position is not a true index of the condition in the erect posture, and I also am convinced of the advisability and necessity of palpation of the kidney in both the prone and vertical positions while making routine physical examination before it is concluded that the kidney is not palpable or tender or that fist percussion reveals no tenderness in the renal region.

Having noted the renal motility in the erect posture, the next problems to decide are (A) Is there any retention or interference with the normal emptying of the renal pelvis while in the erect posture? (B) Does the renal pelvis normally contract and relax when the kidney is elevated by the hand of the operator? (C) Is the kidney fixed or rotated so that stasis results? These questions can most satisfactorily be settled only with a table that places the patient in the standing position. I do not believe that the sitting posture with the thighs flexed will

give as true a degree of motility and resultant dysfunction as the standing position

By this means we then have a correct conception of the physiologic function of the renal pelvis, and are enabled to say, with some degree of accuracy, which patient should be subjected to nephropexy, which will be benefited by the proper kind of abdominal support (as we see many kidneys that come well down to the crest of the ilium or below), and which function properly and have no stasis when elevated to their normal position

EAR COMPLICATIONS IN ACUTE CRANIOCEREBRAL INJURIES

A STUDY OF 476 CASES

By E S GURDJIAN, MD, PH D, DETROIT, MICHIGAN

EAR complications are frequent in cases of skull fracture with brain injury. In a series of over 2,600 cases seen at the Receiving Hospital, Detroit, within a period of five years (1925-1929), there were 476 cases with bleeding or cerebrospinal fluid leakage from either or both ears. The accompanying tabulation (Table I) shows that the left ear is more frequently involved and that with unilateral bleeding the mortality is approximately 38 per cent. With bilateral discharge, the mortality rises to 67 per cent. These figures are astonishingly similar to those reported by Davis (1). However, unlike his experience in cases with cerebrospinal fluid leakage from the ear, the results in this clinic have been much better, the mortality being near 50 per cent. It is undoubtedly true that a certain number of cases with cerebrospinal fluid leakage are not diagnosed because of the presence of blood in the discharge and because, in the majority, the discharge stops very soon after the accident. It should be remembered that there may be bleeding into the tympanic cavity with no associated rupture of the membrane. In such cases, the blood may show in the nasopharynx, escaping the middle ear through the eustachian tube. Bleeding from the ear does not always imply fracture through the petrous bone. There may be a rupture of the membrane caused merely by pressure changes with consequent bulging or retraction of the membrane during the accident. However, as will be brought out later, bloody discharge from the ear is in the majority of cases associated with a fracture somewhere in the skull. In our experience the bleeding usually stops within a few hours after the accident. Occasionally one sees persistent bleed-

ing for several days. In some cases with profuse bleeding the possibility of lateral sinus, jugular bulb, or middle meningeal artery rupture into the middle ear should be kept in mind. In a series of 1,000 cases of skull fracture, Besley (2) found 316 cases with aural bleeding. This is in excess of our findings, but his ratio between left-sided and right-sided involvement compares favorably with ours.

The complications of bloody or cerebrospinal discharge from the ear are otitis media, mastoiditis, and meningitis. In this series there were four cases of meningitis, otitis media occurred nine times, and mastoid infection was present in three cases.

Mastoiditis is a rare complication of skull fracture. While only a limited number of cases have been reported in the literature (see below), probably more would be diagnosed if the possibility of this infection were kept in mind. X-ray examination of the mastoid region is particularly helpful in arriving at a conclusion. It is undoubtedly true that some of the milder cases improve without operative intervention. Because reports of mastoiditis following skull fracture are rare in the literature, the history and the physical findings of our three cases will be given in some detail.

Case 1. Skull fracture following an automobile accident, with bleeding from the right ear, otitis media, and mastoiditis. Operation performed, with recovery.

E H (E-5511), age 24 years, was brought to Receiving Hospital in a semicomatose state, exhibiting bleeding from the right ear. Physical examination showed that the pupils fundi, and extra-ocular movements were normal. There were no cranial nerve palsies. Reflexes were present

throughout Blood pressure was 130/70 The heart, lungs, and abdomen were negative

During her stay in the hospital, the right ear drained continuously, and toward the eighth day the discharge became mucopurulent in character At the same time, the patient developed pain behind the right ear X-ray examination gave evidence of mastoiditis After a week of conservative treatment the patient was operated on A fracture line was found extending across the mastoid region toward the occipital bone, with much purulent material in the mastoid cells The region was curetted out in the usual manner, the dura and the sinus region being exposed during the operation The patient made an uneventful recovery

Comment—The fracture in this case undoubtedly extended into the middle ear, and extension of the middle ear infection into the mastoid cells was much facilitated by the presence of the bony crack uniting those two spaces

Case 2 Skull fracture following an automobile accident, with bleeding from the left ear, otitis media, and mastoiditis Recovery ensued, conservative treatment

A H (E-3479), age 25 years, entered the Receiving Hospital on March 20, 1927, following the accident On entrance she was in a dazed condition, and was unconscious for about an hour There was bleeding from the left ear The neurologic examination was essentially negative, except for the subjective symptoms of headache and drowsiness During her stay in the hospital, the patient's temperature remained normal, but on March 20 there was much pain in the left ear followed by seropurulent discharge X-ray examination of the mastoid region two days later showed definite cloudiness on the left side with moderate destruction (second degree) of the air cells The pain in the ear and the mastoid tenderness subsided the patient's temperature remaining normal throughout It was thought advisable to

treat her conservatively She remained in the hospital for 27 days, with complete recovery

Comment—Here again we have a patient who developed otitis media following bleeding from the ear There was definite mastoid tenderness with positive X-ray evidence of mastoiditis, however, it was justly thought advisable to treat her conservatively because the clinical course was one of gradual improvement

Case 3 Fracture in the mastoid region, following an automobile accident There was no bleeding from the ear, but simultaneous otitis media, mastoiditis, and meningitis Mastoidectomy was performed, followed by death

L C (D-13055), age 6 years, entered the Receiving Hospital following an automobile accident On entrance he was drowsy and had several attacks of projectile vomiting Physical examination showed an abrasion in the right temporal region, the right pupil was larger than the left, but there was no external evidence of bleeding from the ears X-ray examination showed a fracture in the mastoid region on the right side, extending toward the lambdoid suture

During his stay in the hospital the child complained of pain in the right ear, at the same time he exhibited rigidity of the neck Spinal puncture at first showed clear fluid, but later it was purulent The right ear drum was incised with escape of mucopurulent material Mastoidectomy was performed, disclosing this region to be filled with purulent material and showing much destruction of mastoid cells There was daily drainage of spinal fluid During the course of events the patient's temperature rose to 105 degrees F and there was accentuation of the meningeal symptoms, and just before death, which occurred Nov 19, 1926, the temperature was 109½ degrees rectally

Comment—In this case the fracture in the mastoid region was followed by infec-

TABLE I.—ANALYSIS OF 476 CASES OF BLEEDING FROM THE EAR (UNILATERAL, BILATERAL, CERBROSPINAL LEAKAGE)

| Right ear | Left ear | 205 cases | | 98 cases | | 98 cases | | 98 cases | | Complications | | X-ray findings | |

The meningitis was most probably secondary to the mastoid infection. Mastoidectomy was performed with a view to removing the focus of infection to the meninges, unfortunately this was of no help to the patient. Although there was no bleeding from the ear, hemorrhage in the middle ear without rupture of the membrane may have occurred.

The X-ray findings in the series are very interesting. In 379 cases with unilateral bleeding, 282 were examined by X-ray. A majority of the patients who were not subjected to X-ray examination either died a short time after admission or were too ill to sustain the added manipulations. A very small number, indeed, were not examined because of transference to another institution. In 98 cases with bilateral bleeding, 49 were examined by X-ray. Among those with unilateral discharge 93 per cent gave positive evidence of skull fracture, among those with bilateral bleeding, 98 per cent.

At the Receiving Hospital every case of possible skull fracture is examined by X-ray within 12 hours after admission, with the exception of those who are too ill. Routinely, anterior, one base, and two lateral exposures are made in every case. The base exposure brings out particularly the occipital region and the *foramen magnum*. Dr J. C. Kenning, the roentgenologist, insists on as rapid technic as possible, since these patients are in varying degrees of shock, and it is difficult to immobilize their heads for the longer exposure necessary with the Bucky, at least in the majority of the cases. This rapid technic of four views gives very excellent detail of the skull. It is important to focus on the region in which the fracture is suspected, for improper focusing will obliterate fine linear fractures by lapping. All questionable cases of fracture are re-examined, particularly if they show clinical signs of trauma. It is especially advantageous to use the usual mastoid views in some of the

TABLE II—SITE OF FRACTURE IN RELATION TO BLOODY DISCHARGE FROM THE
EAR (313 CASES)

These cases showed X-ray evidence of fracture

cases in which fractures in this region are suspected

With such a technic, over 95 per cent of the cases with aural bleeding were proved to have fracture somewhere in the skull, however, it is important to stress that a great many had fractures in distant parts. The most common roentgenologic finding with aural bleeding was a fracture line in the mastoid region extending toward the vertex or the occipital bone, this being true in fully 50 per cent of the cases. A great many had fractures in the parietal bone, extending down into the middle fossa. Others showed fractures in the region of the foramen magnum, probably extending forward toward the petrous bone. A certain number of the frontal sinus fractures exhibited aural bleeding. A few compound and depressed fractures were accompanied by bloody discharge from the ear, but fractures in the mastoid region predominated and constituted fully 50 per cent of the cases.

DISCUSSION

Thus it is seen that bleeding from the ear is a serious manifestation in craniocerebral injuries. The mortality is decidedly higher than the ratio of the total mortality of the entire series, which is around 25 per cent. The cerebral manifestations in cases with aural bleeding are more severe, however, it

is surprising to note that a certain number show very little derangement of brain function.

The X-ray findings in the series are commendable. Positive findings in cases with unilateral bleeding were 93 per cent, in bilateral, 98 per cent. It must be emphasized that aural bleeding does not always imply fracture in the region of the ear, at least roentgenologically. A great many in this group suffered fractures in other parts of the skull, and the aural bleeding was most probably merely a complication. However, it should be remembered that if a blow is severe enough to cause bleeding from the ear, in 93 per cent of the cases a fracture is found somewhere in the skull, with unilateral bleeding. In cases with bilateral bleeding, there is probably a greater percentage of petrous fractures. The most common roentgenologic finding in this series was a fracture in the mastoid region extending toward the vertex or the occipital bone.

The complications of bleeding from the ear are otitis media, mastoiditis, and meningitis. In the nine cases of middle ear infection seen in this group, the clinical picture presented itself after from a week to ten days. A certain number of these cases recovered with simple drainage. Three had added mastoid infection and one of the latter also developed meningitis. The reason for such a low incidence of otitis media in the

series is explained by the treatment they receive in this Hospital, *i.e.*, the ear is left alone, no irrigations are used, and the patients are not unnecessarily inspected. If there is profuse bleeding, the ear is not packed tightly. In craniocerebral injuries, a case of purulent otitis media is a potential case of mastoiditis. The patient's general condition, temperature, appearance of tenderness in the mastoid region are noted and, if necessary, an X-ray film of the mastoid is procured. Middle ear infection is serious, for meningitis may be one of its sequelæ, such as was true in Case 3, the patient also having a purulent mastoiditis. Although the meningeal symptoms were evident, mastoidectomy was performed in order to remove the focus of infection, but, as practically always is the case, this was of no help to the patient.

The incidence of meningitis in the series is 0.85 per cent. Compared with the incidence in the entire group of 2,600 cases, this complication is more frequent in patients with aural bleeding. Meningitis occurred 19 times in the entire group (0.73 per cent). Any operative approach to curb the appearance of this complication in craniocerebral injuries with aural bleeding or cerebrospinal fluid leakage from the ear seems to us rash surgery. A better approach would be medical preventive measures.

Mastoiditis following otitis media, due to aural bleeding in head injuries, has been described by several authors, and in their paper on this subject Miller and Lauppe (3) review the literature. They found 22 reported cases. Their patient showed the clinical evidence of mastoiditis fully three and one-half weeks after the accident. In this paper we have described three cases, one with co-existent meningitis and two uncomplicated cases. The latter two recovered. One was operated on and the other treated conservatively. The patient who died had a mastoidectomy performed, but he succumbed to the complicating meningitis. Al-

though it is a very rare complication in craniocerebral injuries, mastoid infection, particularly in the presence of otitis media, should be kept in mind. We dare say more cases would be diagnosed if this were remembered. The treatment is either conservative or operative, depending on the severity of the clinical manifestations.

A word should be said concerning complicating facial paralysis in cases of aural bleeding. This is not very common, and unfortunately our records on this point are not complete enough to give statistical data. In a more recent series, to be reported later, the incidence of peripheral facial palsy is around 11 per cent. It should be remembered that facial palsy in these patients may not be evident for a day or two, particularly if the patient is very ill. The bilateral difference in the tonicity of the orbicularis oculi, or a slightly open palpebral commissure on the side of the lesion, may give one the clue as to the presence of the condition. Of course, in the co-operative patient the diagnosis is very simple. The facial paralysis is most frequently a unilateral condition, although very rarely one sees a bilateral facial palsy in a case with bloody discharge from both ears, as was the case in one of our recent patients, a boy five years of age. Rarity of bilateral facial paralysis probably is due to the fact that most of the cases with bilateral bleeding die.

In the majority of the examined cases there was a sensory (taste) change in the anterior two-thirds of the tongue on the affected side. This is most probably caused by pressure against, and distortion of, the chorda tympani nerve as it traverses the middle ear. If it were due to a derangement of the geniculate ganglion region, more patients would show dysfunction of the vestibular system, because the vestibular nerve is in close proximity to the facial in this situation. In view of the fact that a majority recover within a few weeks, the pathogenesis is probably hemorrhage about and within

the facial canal, with pressure neuritis ensuing. In a large percentage of the surviving patients there are no associated vestibular signs of dysfunction, placing the lesion more peripherally than the internal acoustic meatus.

SUMMARY

Aural bleeding in cases of craniocerebral injury is a serious complication. The treatment is conservative both in cases with bleeding and cerebrospinal fluid discharge. The ear should be left alone if it has stopped bleeding. Unnecessary examination may cause the introduction of infection. In cases in which there is still some discharge, the external ear should be carefully cleansed, the wall of the external auditory canal painted with 4 per cent iodine solution, and a mastoid dressing applied either with no packing of the canal or with very loose packing. As long as the patient does not complain of ear ache and there are no unexplainable clinical manifestations, the less done to the patient, the better the results.

1 A total of 476 cases of aural bleeding or cerebrospinal fluid leakage from the ear are reported.

2 The right ear was involved in 36.5 per cent of the total group, the left ear, in 43.1 per cent, there was bilateral bleeding in 20.6 per cent of the cases.

3 In the group examined by X-ray, positive findings in cases with unilateral bleeding were 93 per cent, and in cases with bilateral bleeding, 98 per cent.

4 Otitis media was found in nine cases, meningitis in four, and mastoiditis in three.

5 The mortality was 37.1 per cent with right-sided, 38.5 per cent with left-sided, and 67.3 per cent with bilateral discharge.

GASTRIC TUMORS¹

By MAURICE F DWYER, M.D., The Mason Clinic, SEATTLE, WASHINGTON

APPROXIMATELY 10 per cent of the general run of patients consult a physician on account of gastric symptoms. A study of the causes of gastric complaints in our clinic showed that only 15 per cent of these patients had organic lesions in the stomach or duodenum to account for their symptoms.

Gastric tumors were found in 32 per cent of the total series. These tumors consisted of 111 gastric cancers, 3 benign tumors, 1 hair ball, and 2 cases of gastric syphilis, making an incidence of 1 benign gastric tumor to 39 malignant neoplasms. In a study of a large series of gastric tumors G. B. Eusterman states that in his experience gastric carcinoma is 200 times as frequent as benign tumor.

With the possible exception of the uterus, the stomach is affected by cancer more frequently than any other organ. Notwithstanding the relative frequency and the present accuracy of diagnosis of gastric cancer, this lesion is of such gravity that any series of cases is deserving of detailed study.

In reviewing the histories of a group of patients with gastric cancer, it is immediately apparent that during the past two decades the roentgen ray in the hands of experienced roentgenologists has contributed more to the advancement of the diagnosis of this condition than the combination of all other methods. Yet, owing to the nature of the lesion and the failure to suspect or recognize early signs of the disease, nearly two-thirds of the cases are inoperable at the time the diagnosis is made.

The two chief causes for failure to recog-

nize many early gastric cancers are the anatomic location of the growth and the more or less prevalent idea that the clinical signs of cancer of the stomach always manifest themselves by a sudden onset accompanied by absence of free hydrochloric acid, in a patient previously free of gastric disturbances. The first cause unfortunately cannot be remedied. The second cause can be reduced greatly by reviews of carefully obtained clinical histories of patients suffering from gastric carcinoma.

The location of a gastric cancer has a great deal to do with the early recognition of the growth. A review of our case histories showed that 50 per cent of the lesions began in the pyloric segment, 30 per cent in the middle third of the stomach, and 20 per cent in the upper third. In 80 per cent of the series, the cancer originated in a resectable portion of the stomach. A lesion situated at either orifice produces symptoms indicative of motor disturbances of the stomach much sooner than one located along the greater curvature. Early pyloric obstruction is a fortunate complication because it forces the patient to consult his physician, and vomiting of retained food is a danger sign recognized by even the most inexperienced. The majority of gastric cancers, practically all of which are capable of early demonstration by the roentgenologist, are situated in the pyloric segment or immediately adjacent to it, in an area where they often produce clinical signs, *suggestive*, at least, of the disease. Yet more than half of pyloric carcinomas are inoperable at the time they are diagnosed. Many persons, therefore, are deprived of their only chance of cure or prolongation of life by late diagnosis. Failure to recognize an operable carcinoma is a serious mistake.

¹Read before the Radiological Society of North America at the Sixteenth Annual Meeting at Los Angeles Dec 1-5 1930

Carcinomas situated in the upper third of the stomach and not causing symptoms of dysphagia are easily overlooked unless the roentgenologist is constantly on his guard. When clinical signs suggest an intra-

Fig 1 Case 1 Artist's drawing showing the findings at the fluoroscopic examination. By palpating the partly filled stomach, three small tumors were clearly seen.

abdominal carcinoma, the necessity of careful examination of this portion of the stomach by the use of special technic and fluoroscopic and radiographic examination in various positions cannot be over-emphasized. Most errors in the roentgenologic diagnosis of gastric carcinoma are made in this region. However, malignant growths of the stomach which are difficult to visualize are as a rule inoperable. A question commonly asked the roentgenologist, after the diagnosis of a malignant tumor of the stomach, is whether or not the case under discussion is operable. Unfortunately there is no method by which the operability of a given case can be determined, owing chiefly to the fact that we cannot tell before operation the presence or extent of intra-abdominal metastasis, either peritoneal or in adjacent organs.

The roentgenologist is of great service to the surgeon in determining the approximate

extent of the growth, but there is no definite roentgenologic line of demarcation between the operable and the inoperable case. Surgeons now claim that the surgical accessibility of the growth has a great deal more to do with its removal than the size of the tumor. The general physical condition, the habitus of the patient, and the movability of the stomach are very important factors in determining the amount of the stomach which may be resected.

Not infrequently a patient with gastric cancer is deprived of an early diagnosis because the physician he first consults still believes that the gastric disturbances are not due to a cancer because there is a history of chronic dyspepsia and the analysis of gastric secretions shows the presence of free hydrochloric acid. It is a mistake to assume that gastric cancer always begins with a sudden onset in a patient previously free from trouble with the stomach. A patient presenting a history of chronic dyspepsia from any cause may at the moment be developing cancer, and he is just as deserving of a detailed study to determine or to rule out cancer as is one who consults a physician on account of comparatively recent development of gastric symptoms.

Recently² we made a study of one hundred cases of cancer of the stomach in which particular attention was paid to the onset and duration of gastric symptoms. The review showed that 62 per cent of the patients gave no history of gastric disturbances prior to the onset of the present complaint, and their increasing gastric symptoms averaged only eight months. Examination of these patients showed a large filling defect on the roentgenogram, and in only two instances was there even a trace of free hydrochloric acid. The smaller group, comprising 38 per cent of the series, presented a striking contrast in having a longer early

²M. F. Dwyer, J. M. Blackford, and H. C. Turner, Gastric Cancer, *Jour Am Med Assn*, Nov 9, 1929, **XCVIII**, 1456.

Fig 2 Case 1 Roentgenogram of the partly filled stomach, showing the filling defects produced by the tumors on the posterior wall of the stomach

Fig 3 Case 1 Roentgenogram showing the completely filled stomach. Only one small filling defect can now be noted

history of dyspepsia, averaging ten years before the onset of symptoms characteristic of cancer. These histories of chronic gastric disturbances suggested chronic cholecystitis, gastric ulcer, or the various functional dyspepsias. Gastric analysis was recorded in 31 of the 38 cases, 70 per cent of which showed free hydrochloric acid and occasionally even a hyperacidity. It was of interest to note that in those cases where the original site of the growth could be determined with reasonable accuracy, the group with histories of long-standing dyspepsia were found to have a much larger relative percentage of pyloric cancers than the group presenting short histories. Grave injustice is done a patient if a cancer of the stomach is overlooked simply because he gives a history of chronic indigestion, and free acid can be demonstrated in his gastric contents.

Benign tumors of the stomach are not common. In over five thousand examinations in our clinic, three cases of benign tumors and one gastric hair ball were encountered. While they are not of frequent occurrence, these benign neoplasms are of sufficient importance that the possibility of their presence must continually be borne in mind by both clinician and roentgenologist. A benign gastric tumor may be the cause of atypical gastro-intestinal complaint, and its finding and successful removal by an exploratory operation will recompense and justify a very grave pre-operative diagnosis of malignant disease.

The three cases of benign tumors here reported consist of one with five very vascular mucous polyps, one large fibromyoma, and one leiomyoma.

In reviewing these cases, one is impressed by the lack of gastric symptoms. With the

exception of repeated gastric hemorrhages in the case of the leiomyoma, there were no symptoms indicative of gastric diseases. Gastro-intestinal hemorrhage appears to be a relatively frequent finding in this class of case, however, the number of cases reported in the literature is too small to justify one in drawing conclusions as to the characteristic symptomatology of benign gastric tumors.

Briefly, benign tumors are classified as papillomas, myomas, adenomas, fibromas, lipomas, osteomas, cysts, and adenopapillomas, the presence of the last being commonly called polyposis.

CASE REPORTS

Case 1 A clergyman, aged 48, consulted us in July, 1927, complaining of repeated severe attacks of diarrhea over a period of twenty-five years. In 1903, the patient had had an attack of indefinite upper abdominal distress, associated with jaundice and fifteen or twenty bowel movements a day. The diarrhea was not painful and no blood was seen, but a considerable amount of mucus was passed. In 1924, the gall bladder was removed, and the patient states that, after this operation, his diarrhea was less until three months before consulting us. In 1926, he weighed 175 pounds. In May, 1927, another attack of diarrhea began. He was examined clinically and roentgenologically by his family physician, who found no trouble in his stomach. The diarrhea continued, and he then came to Seattle. On arriving at the Clinic, his condition was so critical that he was immediately placed in the hospital. He had lost 50 pounds in weight and was very emaciated. Laboratory examinations showed a marked secondary anemia, a hemoglobin of 65 per cent, and absence of free hydrochloric acid. Roentgenologic examination showed three small tumors in the upper third of the stomach.

posteriorly (Figs 1, 2, 3), and a diagnosis of benign tumors was made. Examination of the colon was negative. The patient was operated upon July 30, 1927. The stomach was opened by a midline incision and five polyps removed (Fig 4). Three of these had been detected on X-ray examination, one polyp about the size of a lemon and two about the size of a cherry. Each of the additional two found at operation was about the size of a cherry seed.

Pathologic examination showed each tumor to be a highly vascular mucous polyp, covered by a single layer of gastric mucosa. The underlying tissue was mucoid in character, similar to that seen in a nasal polyp.

This patient, whose progress has been closely followed, was last seen one month before the present report. He has been free from diarrhea since operation, a period of 40 months, has gained 45 pounds in weight, and states that he feels perfectly well.

Case 2 An Alaskan miner, aged 67, consulted a physician in October, 1926, on account of loss of 60 pounds in weight, weakness in his legs, and two severe attacks of diarrhea. A considerable amount of blood was passed during the second attack of diarrhea. During the attacks, he occasionally felt nauseated and vomited a few times. He stated that, with the exception of chronic constipation, he had always enjoyed good health prior to the onset of his present complaint. On examination of his blood, erythrocytes 3,130,000, leukocytes 14,000, and hemoglobin, 48 per cent were reported. Physical examination showed a markedly emaciated man, with a palpable epigastric mass the size of an orange. Roentgenologic examination showed a large filling defect on the mid-posterior wall of the stomach, which was thought to be cancer. An exploratory examination was advised.

On opening the stomach, a large pedunculated tumor (Fig 5) about the size of an orange was found attached to the posterior

wall. Its surface was markedly irregular and of a cauliflower appearance. Pathologic examination showed the mass to be a fibromyoma (Fig. 6) with marked inflammatory changes.

tric hemorrhage. She was placed in a hospital, and two transfusions were given. Gastric acidity was normal. The roentgenologic examination, done elsewhere, was said to be negative. Twenty days after the

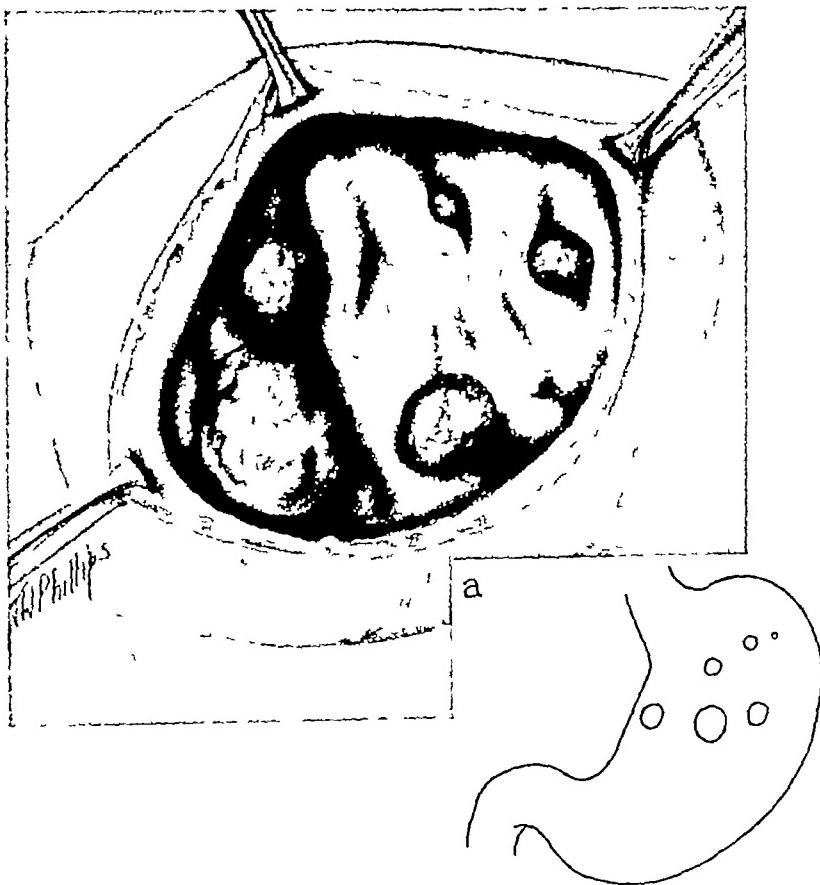

Fig. 4 Case 1 Drawing showing relative positions of the tumors as shown by fluoroscopic examination and the position and relative sizes of the tumors as found at operation.

The patient made an uneventful recovery and returned to Alaska, where he died a year and a half later. According to meager reports obtained from his friends, his stomach was apparently not the cause of his death.

Case 3 A woman, 35 years old, consulted a physician on account of severe gas-

first hemorrhage, another gastric hemorrhage occurred. Sixteen transfusions were given in an effort to get her in condition for operation. A tumor mass was palpated in the upper left quadrant of the abdomen, and, because of the negative roentgenologic findings, the mass was thought to be splenic. Operation was advised. A pedunculated

tumor about the size of a grapefruit was found attached to the posterior wall by a small pedicle. Histologic examination of the tumor showed it to be a leiomyoma

terior wall. The value of the careful palpation of a partially filled stomach during fluoroscopy cannot be emphasized too strongly. If we had not made this method

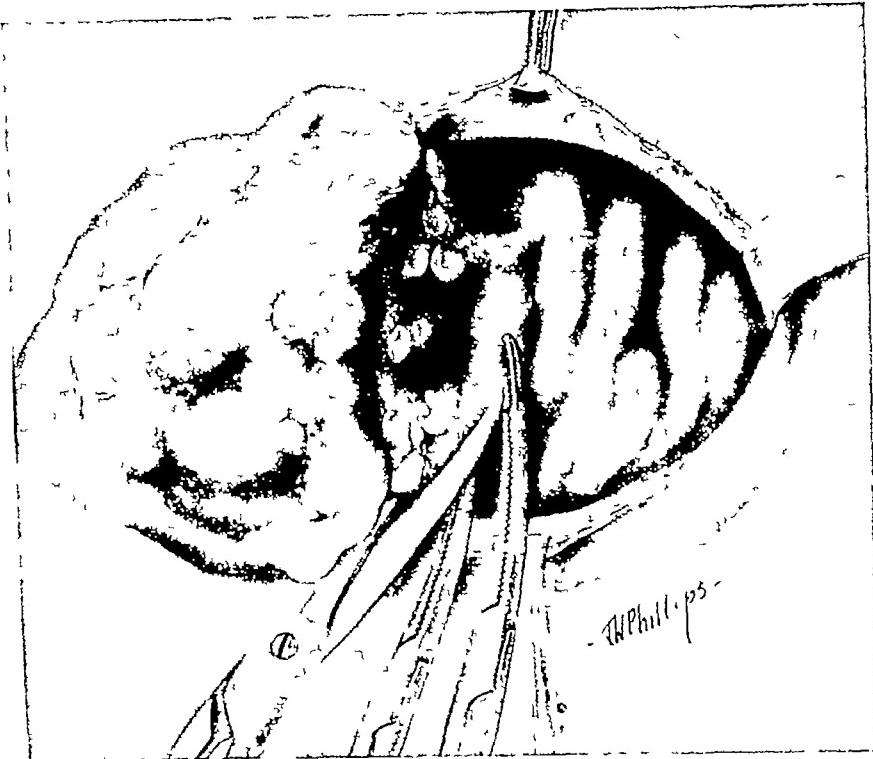

Fig 5 Case 2 Drawing showing the surgical removal of the pedunculated fibromyoma

This patient has been free from symptoms for 9 years

In reviewing these cases, it is readily apparent that the roentgenologic examination was the most important factor in the diagnosis. The clinical signs were very indefinite, and, with the exception of one case presenting severe gastric hemorrhage, there were no symptoms indicative of gastric pathology. All the patients complained of anemia and loss of weight. Two complained of diarrhea, and, in the case with the polyps, severe diarrhea was the sole complaint.

All these tumors were located on the pos-

terior wall. In examination a routine procedure, the small tumors on the posterior wall would have remained undiagnosed.

One must never be hasty in making a diagnosis of inoperable carcinoma. An extensive filling defect seen on a roentgenogram, accompanied by a large palpable epigastric mass, is not always a sign of inoperability. Practically every patient is entitled to an exploratory operation. If for various reasons the mass is not suitable for resection, many will be benefited by an operation for relief of obstruction.

Careful roentgenologic examination of

the stomach accompanied by surgical exploration will go a long way to increasing the number of benign gastric tumors. An early diagnosis is of great benefit to the patient, as a carcinoma may develop on a benign tumor, especially the multiple polypoid variety.

Fig. 6 Case 2 Cross-section of the fibromyoma

A gastric hair ball is a very infrequent cause of a palpable epigastric mass. The case here reported is a large hair ball forming a complete cast of the stomach in a girl 8 years of age.

This child was referred to us 10 years ago on account of a freely movable abdominal tumor. There were no digestive disturbances, the mass was painless and not tender to palpation, the appetite was fair, and there was no loss in weight. Examination of the blood showed hemoglobin 62 per cent, erythrocytes 4,120,000, leukocytes 11,400. The child had acquired the habit of chewing the ends of her curls. Examination of the head showed the hair over the frontal region to be much thinner than elsewhere. From the history of long continued hair chewing and a movable mass in the epigastrium, a clinical diagnosis of gastric hair ball was made.

Roentgenologic examination showed the barium mixture to penetrate slowly between the wall of the stomach and the hair ball.

As the patient continued to drink the mixture, the entire gastric contour was visualized, but the area outlined by the hair ball was faintly shadowed.

The patient was operated upon and a hair mass forming a complete cast of the stomach was removed. At a recent interview, it was found that she has had no after-effects following the experience of hair-eating ten years ago.

SUMMARY

1. The roentgenologist seldom fails to diagnose a gastric cancer, yet, owing to the location of the growth and the failure to recognize early signs of the lesion, the majority of gastric cancers are far advanced at the time of diagnosis.

2. A patient who gives a history of chronic dyspepsia and whose gastric secretions show the presence of free hydrochloric acid may have a cancer of the stomach. This patient is just as deserving of a detailed study to determine or to rule out cancer as is one who consults a physician on account of comparatively recent development of gastric symptoms.

3. In our series of patients with gastric carcinoma 38 per cent give a history of dyspepsia averaging 10 years before the onset of symptoms characteristic of cancer. Seventy per cent of these patients had free hydrochloric acid in their gastric contents.

4. A benign tumor of the stomach, although rare, may be the cause of an atypical gastro-intestinal complaint. Two of the cases here reported complained of no clinical symptoms suggesting a lesion of the stomach. All complained of anemia, loss of weight, and weakness. Persistent diarrhea was practically the sole complaint in one case.

5. The value of careful palpation of the partially filled stomach during fluoroscopy cannot be emphasized too strongly. If this method of examining the posterior wall of

the stomach had not been used routinely, the case with the polyps would not have been diagnosed

6 To quote J C Bloodgood "Do not diagnose inoperable carcinoma from palpa-

tion and X-ray alone Give the patient the benefit of exploration unless there are skin metastases or fluid in the peritoneal cavity Even then, if there is obstruction, operation is indicated "

REVERSE BLOOD FLOW IN HANDS AND FEET TO RELIEVE GANGRENE

An unusual case in which the flow of blood in a patient's hands and feet has been reversed for twenty years has just been reported to the American Medical Association by Dr Bertram M Bernheim of Baltimore

The operation was performed to relieve gangrene which developed as a result of Raynaud's disease, an ailment affecting the smallest arteries and veins When circulation in these is affected, as in Raynaud's disease, the tissues supplied by them do not get proper nourishment, and die

To correct this condition, Dr Bernheim performed an operation linking an artery to a vein in the patient's left leg The blood, which could not get down the diseased artery to the left foot and toes, was able to flow down the vein to the foot Normally, of course, blood flows out from the heart

in the arteries and back through the veins This reversal of blood flow was successful in relieving the gangrene and pain of Raynaud's disease in the left foot Later, when the other foot was attacked, and still later when the disease began to affect the hands, operations were performed to reverse the circulation in these members

The patient, who was 26 years old at the time of the first operation, is now about 45 and in excellent health generally, Dr Bernheim found on examination nearly twenty years after her last operation However, pain has returned and gangrene set in again in the remaining toes of the feet and in one finger The reason for this cannot be determined, nor can the final outcome of the case be predicted, Dr Bernheim stated The openings from arteries to veins in the arms appear still to exist and have probably prolonged the patient's life and health for many years

DIVERTICULOSIS OF THE COLON¹

By FRANZ V GROEDEL, M.D., BAD NAUHEIM, GERMANY

DIVERTICULA are small pulsion pouches or hernia of the mucosa or sub-mucosa (diverticula spuria), or more rarely pulsion pouches of all layers of the abdominal wall of the colon (diverticula vera). Diverticulosis is more common in men than in women. The diverticula are generally situated near the edge of the mesentery. These pockets almost always occur in the sigmoid flexure, more rarely in the rectum. They have been thought to be related to constipation and fecal stasis, so common are they at these points. They can exist for a long time without giving rise to symptoms, but here, as in the vermiform appendix, retention can lead to suppuration and perforation. Aschoff distinguishes two forms (1) Congenital, and (2) acquired, or true and false diverticula. Aschoff (1) also finds that the sigmoid flexure is the most common site.

The diagnosis of diverticulosis is made by X-ray examination. Not much has been heard from radiologists in the literature of Germany (2) about diverticulosis, although most of us have come across this peculiar condition of the bowels.

The following clinical notes may be of interest. A 71-year-old man had been a patient of mine for two years. He had never had any serious illness, but had complained of flatulence and abdominal pain and discomfort off and on for four years, accompanied by loss of weight. On X-ray examination and test meal three years ago, the only findings were abnormally increased stomach motility and achylia. At the time, this condition was considered to be due to pyorrhea, from which he was found to be suffering. In spite of dieting and treatment,

loose stools and attacks of diarrhea soon after meals persisted.

On X-ray examination the following points were noted:

1 Immediately after the barium meal the stomach was completely pressed up against and adherent to the liver. Neither the pylorus nor the duodenum was visible. A few coils of intestine were overfilled and bulging.

2 One and a quarter hours after the meal the stomach was empty but still adherent to the liver. Behind it a fairly normal bulbous was seen. The upper coils of intestine were considerably dilated. The bulk of the barium meal was in the small intestine.

3 Three and a half hours after the meal the cecum and ascending colon were filled. The small intestine was very irregularly filled. Bubbles of air indicated the shadow of the transverse colon, which was displaced upwards.

4 Eight hours after the meal the small intestine was quite empty. The barium mass was collected in the rectum. The cecum was still full of air and the appendix was filled. The only signs of the transverse colon and the colon descendens were round bubbles of air and round spots of shadow. Round pulsion pouches the size of coffee beans were seen in the S romanum.

5 Twenty-five hours after the meal the whole large intestine was visible and contrasting shadows showed its whole course, the ingested food, and the much thinned and retained contents. Numerous pockets were seen over these thin shadows, just at those points which were filled with the barium porridge twelve hours before. The appendix was not quite empty.

6 Thirty-five hours after the meal the appendix was still filled, although complete

¹Read before the Radiological Society of North America at the Thirteenth Annual Meeting at New Orleans La Nov 28-Dec 2, 1927

evacuation of the bowels had occurred. Near the appendix, two large pockets in the right flexure, six diverticula in the transverse colon, and seven in the colon descendens were seen. In the flexure of the S romanum, one large pocket was seen and numerous diverticula in the S romanum.

Diagnosis—Extensive perigastric adhesions of the pylorus region, probably from some cholecystitic process, and diverticulosis of the whole colon (*diverticula vera*).

Shortly after the diagnosis was made, the patient was taken ill with symptoms resembling those he had once previously had, i.e., pain in the region of the sigmoid flexure with temperature. There was considerable tenderness to pressure on this region, and over the course of the whole colon. It was evidently an acute attack of diverticulitis, very similar to an acute appendicitis.

Noteworthy in this case are the extensive distribution of diverticula over the whole colon, the large size of the several diverticula, and the very long persistence of the diverticular shadows.

In his monograph, Strauss (3) maintains that the diverticula of the large intestine can

be distinguished only by X-rays, with the aid of rectal enemas as the only fluid matter that can enter the diverticula. According to De Quervain they are best seen when a part of the enema has left the rectum.

In all cases, Strauss is of the opinion that extreme care and careful criticism should precede diagnosis.

Because in the case cited there was little or no difficulty in demonstrating the condition, we are of the opinion that it is only the diverticula spuria that cause any difficulty of demonstration, and we believe that the rarer and more important diverticula vera can be demonstrated with perfect ease and certainty by the improved technic of to-day.

TUMORS OF THE MALE BREAST, BASED ON A STUDY OF THIRTY-ONE CASES

By BERNARD F SCHREINER, MD, FACS

State Institute for the Study of Malignant Disease, BUFFALO, N Y
Burton T Simpson, MD, Director

DURING the years 1914 to 1931 (June), there were 17,486 cases admitted to our tumor clinic for examination and treatment. Included in this number were 1,664 diseases of the breast submitted for study, treatment, and observation. Only 31 of these breast lesions were in males. For this reason, it was thought of sufficient interest to tabulate and record the pathologic conditions for which advice was sought.

The following is a comparative table:

| PATHOLOGIC CONDITION | MALES | FEMALES |
|---------------------------------|-------|---------|
| <i>Malignant Lesions</i> | | |
| Carcinoma | 15 | 1,240 |
| Epithelioma skin | | |
| Pearl cell | | 1 |
| Basal cell | | 1 |
| Paget's disease | | 14 |
| Sarcoma | 1 | 4 |
| <i>Benign Lesions</i> | | |

number of the cases reported and summarized his findings. It is apparent, from the relatively small number of cases reported, that carcinoma in the male breast is less frequent than in the female breast.

Various observers from time to time have given the impression that carcinoma of the male breast was not so malignant as carcinoma of the female breast. This apparently is an erroneous idea as is shown by subsequent observations of the cases which Wainwright has studied and from observations of our own 15 cases.

Ewing (3), in his book on Neoplastic Diseases, states that the frequency of cancer of the male breast is from 0.8 per cent to 6.0 per cent of all breast cancer, quoting Williams and LaForgue as authority. Deaver and McFarland (4) in their series estimate that 1.5 per cent of the malignant breast tumors and 2 per cent of the benign tumors occurred in men, and that 80 per cent of the tumors of the male breast are malignant. Our statistics show that 1.25 per cent of all the breast cancers admitted were in the male, and that 50.1 per cent of all male tumors were malignant.

Chronic inflammatory lesions often precede the development of malignancy and it is for this reason that benign lesions in the male breast were treated rather radically by amputation of the breast.

Of our 31 cases of tumors of the male breast, 15 were benign and 16 malignant. Among the 16 malignancies, one was a spindle-cell sarcoma. This man, who was 77 years old, gave a history of soreness, drawing sensation, and a small hard lump for eighteen months prior to admission to the clinic. At the time of examination, he

In a recent paper, Neal and Simpson (1) brought to our attention the various diseases of the male breast that were encountered in 5,000 cases. In 1927, Wainwright (2) made an exhaustive study of the literature, both historical and recent, of carcinoma of the male breast. He then analyzed a large

had metastases in the axilla. The tumor was removed surgically and then treated with high voltage X-ray. He died from recurrence and old age four months later.

The age incidence of the 15 cases diagnosed as carcinoma is shown in the following table:

| 30-39 | 40-49 | 50-59 | 60-69 | 70-79 | 80-89 |
|-------|-------|-------|-------|-------|-------|
| 2 | 2 | 5 | 1 | 4 | 1 |

The youngest was 33 and the oldest 89; 11 occurred after the age of 50.

The history of duration of the lump varied from 1 month to 20 years as shown below:

| | |
|--------------------|---|
| Less than 6 months | 3 |
| 6 months to 1 year | 3 |
| 1 to 2 years | 3 |
| 2 years | 1 |
| 3 years | 2 |
| Over 4 years | 1 |
| Twenty years | 2 |

Wainwright, in his study, also reports several cases with a history of 20-year duration of the lump before treatment.

Biopsy or section was obtained in 12 cases, of these 11 showed scirrhous carcinoma, and one, adenocarcinoma. In the other cases, the lesions were so far advanced that a definite clinical diagnosis could be made without section.

Upon examination, four cases were found to be ulcerating, of these, three were in far advanced stages, and one, in a patient in an early stage in whom only the breast was involved. There were three other cases in which the tumor was confined to the breast and no nodes were palpable, three cases in which only axillary nodes were palpable in addition to the breast tumor, and five other cases in which there were widespread metastases. Four cases were post-operative, recurrent, with widespread metastases. Definite mediastinal involvement was shown in four cases, definite skin metastases, in

Fig 1 Carcinoma of the breast with aleukemic leukemia, at time of admission to the Institute

Fig 2 The same patient, one year after operation and treatment.

three cases, and general carcinomatosis, in one case.

TREATMENT

Three cases (admitted between 1915 and 1920) were treated with low voltage filtered X-ray with unfiltered X-ray over the ulcer, two had high voltage X-ray only, seven had removal of the tumor surgically, followed by high voltage X-ray, and one had high voltage X-ray, radium pack, and implantation of radon seeds in the breast. Two were not treated; one of these had amputation elsewhere but the result of this operation is not known as he did not return to the Institute.

Three of those treated surgically had amputation before admission, they were re-

current, far advanced, when admitted Two died in less than a year and one, somewhere between one and two years

Three cases in which surgery was done at the Institute, no nodes being present at the time of operation, have been well four years, one year, and two months, respectively, or since the time of operation

In one of the cases treated surgically, there were metastatic nodes in the axilla at the time of operation This patient has been well since treatment—two years, seven months

Of those treated by irradiation alone, none was an early case and all but one are dead This one has been treated for two years and five months There has been no progression of the disease The patient refuses amputation though he has been urged several times to submit to it The others died four in less than a year, and one between two and three years

Of these 15 cases, only eight are available for 5-year study Only one had no lymphatic or other involvement This patient has been well for four years He did not submit to amputation until two years after admission, during this time he had high voltage X-ray Section at the time of operation showed carcinoma The other patients have all died

Two of the cases of carcinoma of the breast had complications One patient (Fig 1) had large lymph nodes in the axilla which, at the time of operation, were found

to be hyperplastic Subsequently, the patient developed nodes in the neck The blood findings, 16,800 leukocytes with 75 per cent lymphocytes, confirmed the diagnosis of aleukemic leukemia One, who on section showed adenocarcinoma of the nipple, had had an epithelioma of the penis which had been well for six and one-half years, and an epithelioma of the left corner of the mouth, which had been well for two years

CONCLUSIONS

1 Carcinoma of the male breast is about 1 25 per cent of all cancers of the breast in our series

2 Carcinoma of the male breast is an uncommon disease, sarcoma is rare

3 Carcinoma of the male breast is as malignant as carcinoma of the female breast

4 This disease occurs, as a rule, late in life

5 With few exceptions, patients in our series applied for treatment late in the course of the disease

THE CONCEPT OF DOSAGE AND THE DEFINITION OF THE r-UNIT (ROENTGEN UNIT)

By DR. RICHARD GLOCKER, Professor für Röntgentechnik und Vorstand des Röntgenlaboratorium an der Technische Hochschule, STUTTGART, GERMANY

Translation by GEORGE L CLARK, PH D, Department of Chemistry, University of Illinois, Urbana

THE two attributes for characterizing and measuring an electromagnetic ray (light, X-rays, γ -rays) are the wave length and the intensity. Two rays with equal wave length are qualitatively equal, they possess, for example, equal penetration power. The measurement of wave lengths is made by the spectrographic method. The radiation intensity is a measure of quantity, it corresponds to what is ordinarily termed quantity of radiation. In the newer definition, the radiation intensity is that radiation energy which strikes in one second upon a surface of 1 sq cm perpendicular to the direction of the ray. An absolute measurement of intensity for X-rays is very difficult and depends upon the very minute increase in temperature resulting from the complete absorption of the rays in any irradiated object. For all other effects of X-rays (ionization, photographic plate, fluorescent screen, selenium cell, skin erythema, etc.), the degree of action depends on the radiation intensity and also on the wave length. On this account a different fraction of the initial radiation intensity for different wave lengths is transformed in the irradiated medium into other energy forms. The action is, therefore, independent of the wave length only when the beam of given initial intensity inclusive of the secondary rays arising therefrom is completely absorbed in the irradiated material—a condition which can be realized practically only with methods based on the thermal effect. How great can be the difference in the dependence of the sensitiveness of different methods of measurement upon the wave length is demonstrated in Figures 1 and 2.

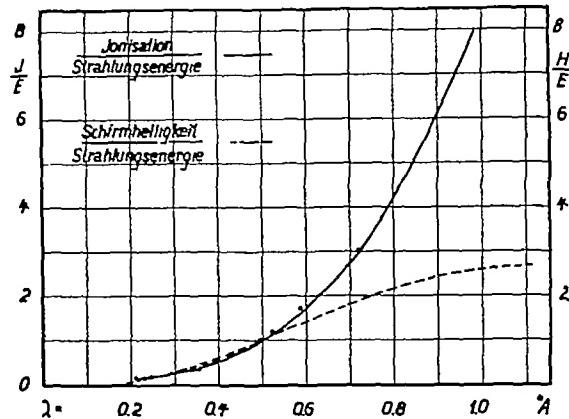

Fig. 1

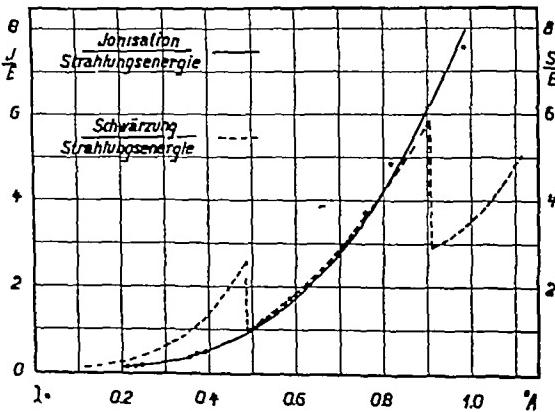

Fig. 2

If different homogeneous rays, i.e., rays which possess only a single wave length, fall simultaneously with equal intensity upon an air ionization chamber, a fluorescent screen, and photographic plate, the brightness of the screen changes much less with wave length than the ionization current (1). Upon comparison of the ionization and blackening of the photographic plate, it is especially noteworthy that the photographic sensitiv-

ness changes with sudden jumps in two places (0.49 and 0.91 Ångström unit) Since these wave lengths coincide with the discontinuities in absorption coefficients of silver and bromine, the two effective constituents of the photographic emulsion, it must be concluded that the photographic action is closely connected with absorption Not only for the photographic effect but also in other cases, for example ionization, the following principle holds the action of rays changes with wave length in the same way as the intensity of the absorbed portion of the incident rays changes Exceptions occur in the region of very short wave X-rays, when the Compton effect is appreciable, and in the case of the excitation of characteristic fluorescent rays of the irradiated material A very recent investigation has now demonstrated that all known physical and chemical effects (2) are governed by a simple law, the law of electron transfer The effect changes with the wave length in the same way as the fractions of the incident radiation energy transformed into the energy of photo- and Compton electrons This value may be calculated for certain chemical compositions of a material from physical data (absorption coefficient recoil coefficients, etc.) The good agreement between theory and experiment is shown in Figure 1 for the case of ionization, the circles corresponding to experimental values, the curve itself being theoretically calculated The earlier mentioned law of proportionality of the effect in the absorption constitutes a special case of the general law of electron transfer if no characteristic radiation is generated, the whole absorbed energy is transformed into the energy of photo-electrons and both magnitudes change in the same way with wave length, further, if the radiation is not of such short wave length that Compton electrons with appreciable energy appear, the chemical or physical effect coincides with the energy of the photo-electrons alone

The knowledge of the fundamental laws of physical and chemical radiation effects is of important use for a discussion of the dosage problem The idea of dosage arose from the immediately practical necessity to provide for therapeutic irradiation a physical measurement determined independently of the wave length of the rays for the intensity of the biologic reactions, especially for the skin erythema Since the primary process of a biologic effect is a physical-chemical one, it is to be expected that equal intensities of two qualitatively different X-rays would possess different biologic effectiveness Apart from the already mentioned difficulties of an absolute intensity measurement, such a method would also constitute an entirely impracticable dosage measurement for therapy, since the biologic action changes from wave length to wave length even for conditions of equal incident intensity The aim of practical dosage measurement must, therefore, consist in the selection of a radiation effect as the basis for dosage measurement which changes with the wave length in the same way as a given biologic reaction, for example, the production of skin erythema The measurement of the ionization current in air under conditions in which the wall effect is eliminated has served in this respect empirically as the most important method of dosage measurement apart from very soft rays (Bucky's Grenz rays) for which the inhomogeneity of absorption for different parts of the skin plays an important part, a complete parallelism between skin erythema and air ionization existing independent of the quality of the radiation (3)

The conception of dose was first formulated exactly by Christen (4) in the year 1913 *The physical dose is the radiation energy absorbed in a volume element of a body during the time of irradiation divided by the magnitude of the volume element* Since the radiation energy falling upon the

different deep lying points of a body is greatly different, it is essential to proceed to the definite establishment of such a small zone of the irradiated body that within this zone an average constant radiation energy can be calculated with sufficient accuracy. In this case instead of the exact expression for the radiation intensity absorbed in the thickness "D" for an X-ray beam with absorption coefficient

$$(1) \quad I_1 - I_2 = I_1 (1 - e^{-\mu D})$$

it is permissible to make the approximation (expansion of the exponential function to a series)

$$(2) \quad I_1 - I_2 = \bar{\mu} D$$

The total absorption radiation energy in a cubic volume element with the surface "Q" and the height "D" in the exposure time "t" is then

$$(3) \quad \bar{\mu} D Q I_1 t$$

After division by the size of the volume element "Q D" there is obtained by definition the dose "X". It is, therefore,

$$(4) \quad X = \bar{\mu} I_1 t$$

In other words the dose "X" is equal to the product of the absorption coefficient, the intensity of the incident ray, and the exposure time

Against the dose idea of Christen it may be objected that it is practically unusable since one is ordinarily not in the position to measure the intensity I_1 by simple technical methods. Nevertheless this idea has been of greatest usefulness for dosimetry. It contains an expression at that time by no means experimentally capable of verification accounting for how the biologic action changes with radiation quality. It gives, therefore, a lead for finding out a physical effect which is characterized by the same dependence upon wave lengths as skin erythema.

It is evidently necessary to find the effect upon a material which corresponds in its

absorption properties to tissues or water. Since the absorption coefficient depends not only upon the wave length but also upon the density and the atomic number of the elements constituting a material, it is to be expected that the air, consisting of the light elements, oxygen and nitrogen, should possess the same absorption properties as the tissues, consisting of organic compounds of carbon, nitrogen, and oxygen.

Experimental researches have fully substantiated this expectation. At the second International Congress of Radiology in 1928, as an outgrowth of the work of Szilard, Friedrich, Behnken, and others, the measurement of air ionization was accepted as the basis of international dosage measurement and a definition was given of the unit of dosage designating a roentgen unit and written in abbreviated form as "r". *The absolute unit of X-ray dosage is derived from that X-ray energy which, by the irradiation of 1 cubic centimeter of air at 0° centigrade and 760 millimeters mercury pressure, when the secondary electrons are fully utilized and the wall effect of the chamber is avoided, produces such a degree of conductivity that one electrostatic unit of charge is measured at saturation current.* How does this definition of dose compare with that of Christen? If an exception is made, first, of the short wave length region on account of Compton scattering, it is true as was explained in the introduction that the air ionization is proportional to the radiation intensity absorbed in the volume unit of air. The product of the ionization current and the time of irradiation (5) is, therefore, a measure for the dose in air in the sense of Christen's definition. Since the dependence upon wave length of the absorption coefficients of light atomic substances is the same, the dose in air is proportional to the dose in the tissue. It follows that the roentgen unit, aside from a practically negligible proportionality constant (6), measures the

physical dose in the tissue as was first defined by Christen

The observation found in the literature that the introduction of the roentgen unit involved the proposal of the original definition of the conception of dose is, therefore, an error. The knowledge of the fundamental laws of physical and chemical action of X-rays leads to the possibility of so extending the idea of dose that it will apply for all X-ray wave lengths. As was indicated in the introduction, the proportionality of the effect to the absorbed radiation energy is only a special case under certain assumptions of the general law that the electron transfer (total kinetic energy of the liberated photo- and Compton electrons) is determinative for the physical and chemical effects and their changes with wave lengths. Upon analogous grounds, the same thing would be expected for the biologic action. Against the conception that X-rays act upon the cells in such a way that, first, electrons are liberated from the irradiated atoms, and, then, the action of these electrons gives rise to the initiation of cell destruction, have appeared researches of Politzer and Pauli (7) in which it has been discovered that in the irradiation with cathode rays of salamander larvae a kind of nuclear pectosis (stainability of spindle fibers) was found which was never observed in irradiation with X-rays. It must be concluded from this that the action of electrons and of X-rays is of a different type. More recently (8), however, it has developed that it is possible to obtain the same effects also with X-rays provided that extremely large dosages, several hundred thousand r in a few minutes, are applied in short time. Thus this experimental exception refutes the earlier conclusion.

When it is borne in mind that the definition of the roentgen unit is derived from ionization in air and that the validity of the proportionality of the effect with the elec-

tron transfer has been experimentally proved (Fig 1), it is possible in two different ways to proceed to the following generalization of the Christen definition of dose. *The physical dose is the electron energy (kinetic energy of photo- and Compton electrons) liberated by the action of X-rays in a volume element of the irradiated body during the time of exposure divided by the size of the volume element.* In equation 4 above in place of absorption coefficient $\bar{\mu}$ is substituted the expression $\alpha\bar{\mu} + \sigma_r$ in which α means the fraction of the absorbed energy which is changed into the energy of the photo-electrons. In the region of the ordinary therapeutic X-rays, α is made equal to one on account of the absence of the characteristic radiation in biologic objects. The recoil coefficient σ_r is an expression for how much of the X-ray energy scattered in the Compton effect is transformed into the energy of Compton electrons. For the wave length region ordinarily utilized in therapy, the dose and the unit of dose are clearly established. In going over to the extremely long wave X-rays, 4 Å U and more, however, the following difficulty arises out of the definition of the roentgen unit upon the basis of air ionization: the absorption edge of argon at 3.86 Å U results in the absorption in air changing discontinuously at this wave length, whereas the same phenomenon does not take place in tissues or water. The dose in air and the dose in the tissue are, therefore, no longer proportional to each other. The magnitude of the argon discontinuity can be determined with the help of new gas absorption measurements of Wornle (9). The chemical composition of air in weight percent according to Ramsay (10) is as follows:

| O ₂ | N ₂ | Ar | Kr | X | Ne | He | CO ₂ |
|----------------|----------------|-----|-------|-------|---------|----------|-----------------|
| 23.2 | 75.5 | 1.3 | 0.028 | 0.005 | 0.00086 | 0.000056 | 0.046 |

Among the rare gases only argon has an appreciable effect upon the absorption. The ratio of the mass absorption coefficients of

air containing argon, and argon-free air has the value 1.088 for wave lengths shorter than 3.86 Å U and 1.1 for wave lengths longer than 3.86 Ångstrom units. Since, according to Gartner (11), the work of ionization in argon is about 19 per cent smaller than in air, the contribution of the argon atoms to total ionization is greater than corresponds to their portion of the absorbed energy. For long wave rays above 3.86 Å U, ionization in argon-containing and in argon-free air is equal, while below the argon absorption edge the ionization in argon-free air is only 0.84 as great as in ordinary air. Now since biologic objects in general contain no higher atomic elements in such concentrations (12) that their absorption edges are appreciable in comparison with the total absorption, this result means that for wave lengths less than 3.86 Ångstrom units, for dosage measurement in r units, the dose in biologic objects is about 18 per cent greater than the number of r units indicates. The dose so measured is too small. Taking into consideration the effect of the krypton absorption edge, this number is increased about 2 per cent more (13). Although at the moment the question of the extension of the definition of the roentgen unit for the extreme wave length region has no very important meaning for therapy, a consideration of the increasing application of long-wave rays in biologic researches (Lacassagne and Holweck, 14, Wyckoff, 15) will very soon necessitate a final and definite solution to the problem. On this account it must, therefore, be established that magnitude of the dose will not change for all therapeutically used X-ray wave lengths. For the definition of the r unit, all gases can be utilized which in the long wave length region are free from absorption edges, for example, a nitrogen-oxygen mixture of 23.5 weight per cent O₂ and 76.5 weight per cent of N₂, or carbon dioxide. Carbon dioxide is

proposed upon the grounds of practical simplicity. A new wording of the definition of the roentgen unit would, therefore, run somewhat as follows: *The absolute unit of the X-ray dose is derived from the fraction X of that X-ray energy which, when the secondary electrons formed in the gas are fully utilized and the wall effect of the chamber is avoided, produces in one cubic centimeter of carbon dioxide gas at 0° centigrade and 760 millimeters mercury pressure such a degree of conductivity that one electrostatic unit of charge is measured at saturation current.* The magnitude "X" can be determined by simple comparative measurements once for all cases with an ionization chamber filled with air and with carbon dioxide. Since the effective atomic numbers of both gases are approximately equal, "X" must correspond approximately to the ratio of densities, namely, the number 0.66. With this new wording, a real proportionality between dose in standard gas and dose in biologic object should exist. This substantiates the possibility of undertaking all practical dosage measurements for therapeutic irradiation with air ionization chambers.

SUMMARY

1 It is shown that the formulation of the idea of dose given by Christen and the definition of the roentgen unit agree with one another.

2 An expanded definition growing out of the fundamental laws of physical and chemical effects of X-rays is given for the concept of dose.

3 For support of the proportionality of the dose in the biologic object and the dose in the standard gas, even upon the long wave length size of the argon absorption edge, a new wording of the definition of roentgen unit is proposed.

HORMONE PRODUCTION MAY DEPEND ON MANGANESE

Studies indicating that the formation of a hormone by the pituitary gland is in some way related to the manganese of our daily diet have been described by Dr E V McCollum, of the Johns Hopkins School of Hygiene and Public Health, at the meeting of the National Academy of Sciences. He pointed out the relation of iodine to the thyroid gland, of calcium to the parathyroid glands, and said that apparently another glandular system had been linked with an inorganic element which is essential to the diet.

Rats deprived of manganese exhibit strange behavior and bodily changes, Dr McCollum and his associate, Dr Elsa Orent, have found. The sex glands of the male rats degenerate until complete sterility results. The females, however, continue to have litters of living young but do not show any sign of ordinary maternal solicitude. Normal mothers seem to detect something

wrong with the young of manganese-free mothers and abandon them, although normal rats will ordinarily care for each other's young when the litters are exchanged. "The addition to the manganese-free diet of as little as five-thousandths of 1 per cent of manganese results in correcting the behavior of the female rats toward their young," Dr McCollum said.

Other workers have reported that male sterility in middle life is related to deficiency of the pituitary hormone, and that the pituitary gland stimulates milk secretion. Dr McCollum suggested that since manganese-deprivation had the same effect, the dietary manganese may be related in some way to hormone formation by the pituitary gland. However, there is no need to worry over possible lack of manganese, as one worries over lack of vitamins, it appears, for Dr McCollum reported that at the beginning of the experiments great difficulty was encountered in removing manganese completely from the diet.—*Science Service*

INTERNATIONAL COMPARISON OF X-RAY STANDARDS¹

By LAURISTON S TAYLOR, WASHINGTON, D C

Abstract—Direct comparisons between the X-ray ionization standards of the United States, England, Germany, and France are described. The small guarded field ionization chamber was used as the working standard and transported to the several laboratories. Careful check of the instrument calibration at each laboratory showed no change due to transportation. Complete corrections were made for air absorption, differences in current measurements, and differences between chamber diaphragms. The final agreement between

the United States, English, and German standards was ± 0.5 per cent. The ratio between the international roentgen and Solomon's unit for hard radiation (HVL greater than 0.75 mm Cu) was 2.29. As a result of diaphragm discrepancies found in England, a study of diaphragm measurements was made. It was found that lead diaphragms tended to warp with age, rendering difficult an accurate determination of their area. Plug gauge and micrometer microscope measurements were averaged for the final results.

I INTRODUCTION

THE unit of X-ray quantity known as the "roentgen" has within the last few years become very generally used in applied radiology. In the meantime, many investigators have studied the problem of devising an equipment which will unambiguously measure an X-ray beam according to the definition of the international roentgen as proposed by the Second International Congress of Radiology in 1928² and many important features overlooked by the earlier investigators have been brought out.³ There has at the same time been set up in the national laboratories of England, Germany, and the United States standard open-air ionization chambers in terms of which dosage meters for the particular country are calibrated.^{4, 5, 6}

Other countries, not having centralized

standardization laboratories, have designated certain private or state institutions as recognized custodians of the standard. In France, Dr I. Solomon, at L'Hôpital St Antoine, is the official custodian.

Since the different national standards have been designed and constructed independently, it is natural to find that no two are exactly alike, even though the basic principles involved in all are the same. On account of these differences the most obvious question was how closely these several standards agreed.

The first attempt at comparison was made in 1927 by Behnken.⁷ For this purpose he carried a pair of carefully controlled thimble chambers, which had been calibrated against his standard, to several laboratories for comparison. His results revealed a difference between several American laboratories (not including the Bureau of Standards, since we had no X-ray standardization equipment at that time) and the Physikalisch-technische Reichsanstalt of some ± 4 per cent. More recent studies^{8, 9} have shown that an ambiguous calibration is ex-

¹Preliminary report read by L. S. Taylor at the Third International Congress of Radiology, Paris July 29, 1931.

²The roentgen is defined as "the quantity of X-radiation which when the secondary electrons are fully utilized and the wall effect of the chamber is avoided produces in one cubic centimeter of atmospheric air at 0° C. and 760 cm mercury pressure, such a degree of conductivity that one electrostatic unit of charge is measured at saturation current."

ceedingly difficult Behnken's comparison measurements were made with a magnesium thimble chamber which, therefore, had a considerable dependence upon the radiation quality as compared with an open-air ionization chamber. The impossibility of reproducing the necessary radiation qualities in the different laboratories consequently influenced accuracy of the measurements in an unfavorable way.

It appeared, therefore, that a direct comparison among the standards themselves would be the only reliable method.¹⁰ This has heretofore been practically precluded by the very great weight and size of these open-air standards. The guarded field ionization

chamber developed in this laboratory^{11, 12} appeared, however, to be sufficiently compact to transport, so the Bureau arranged for a comparison with the national laboratories of England, Germany, and with Dr Solomon's laboratory of France.

II PORTABLE X-RAY STANDARDIZATION EQUIPMENT

(1) Description of Apparatus

The working standard used in these comparisons was a small guarded field ionization chamber previously described^{11, 12} though some minor modifications from that

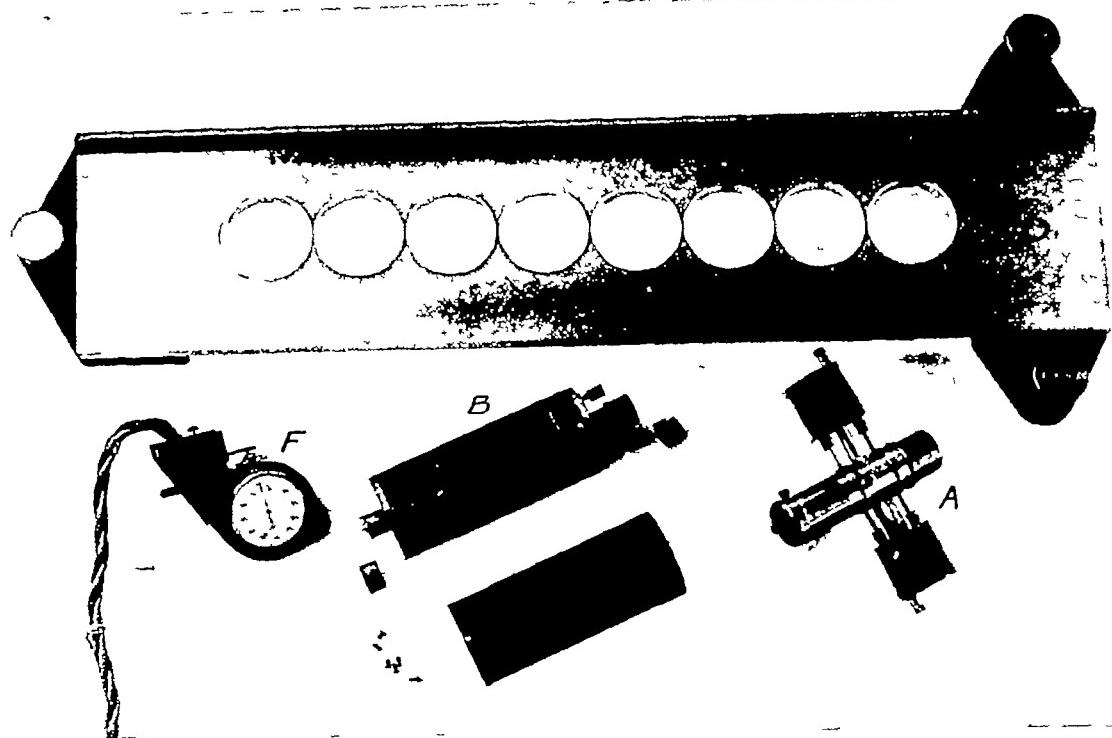

Fig 2 Accessory equipment.

description were made to facilitate the more ready alignment in the X-ray beam. At the same time, the beam was isolated from the guard wires by reducing their number from 12 to 8, which permitted a spacing of 1.8 cm between the central pair. With the chamber diaphragm of only 0.8 cm diameter there was little likelihood of the beam striking the wires unless the chamber was placed abnormally close to the tube. The change in spacing of the guard wires necessitated, however, an increase of 3 cm in the length of the surrounding box to maintain a uniform electric field between the collector plates. To insure ruggedness the older potential dividing resistors of carbon were replaced by wire-wound resistors.

The current measuring system used (*E*, Fig 1) has already been described^{13, 14}. In

this, the electric charge furnished by the ionization chamber is entirely localized in a condenser which has one plate connected to the ionization chamber collector electrode and the other to a source of continuously variable potential. The localization is effected by maintaining the receiving line at a constant potential by properly changing the variable potential. This change in potential measures the accumulated charge. The null reading electrometer is connected to the ionization chamber (*I*) by a flexible rubber cable (*C*) surrounded by an earthed copper sheath. It may be noted that since, in the current measurements, the potential of the system is maintained at zero, cable leakage plays no part in the magnitude, but merely affects the sensitivity.

To derive the current, two different timing devices were used as circumstances demanded. The first was a magnetically operated lead shutter (*A*, Fig 2) to fix the ex-

posure interval to the X-ray beam entering the ionization chamber. The second was a magnetically operated switch (*B*), placed in the electrometer circuit to disconnect the measuring system from the ionization chamber. The second method is less desirable than the first, because breaking the connection changes the capacity of the system, this requiring that the electric switch be operated only when the electrometer indicates zero potential, and that no adjustment of the compensator be made after opening the switch.

Both shutter and magnetic switch are operated and timed by means of a combined stop watch and two-way switch (*F*, Fig 2). The switch is adjusted to operate at the instant the stop watch is started and stopped, during which interval the operator balances the ionization current by changing the voltage *V* of the compensating condenser. The ratio of the compensating voltage *V* to the interval *t* is proportional to the ionization current.

Saturation voltage for the ionization chamber was supplied from a compact 2,000-volt kenotron rectifier (*R*, Fig 1), having a filter capacity of 1 micro-farad. The current drawn off by the potential divider for the guard wires, being only 4×10^{-4} amperes, introduces no appreciable ripple in the saturation voltage.

The ionization chamber was mounted on a swivel table and short cross slide (*T*), for adjustment in a direction at right-angles to the beam in the horizontal plane, and the cross slide in turn mounted on an aluminum optical bench (*BN*) for adjustment along the beam. Two such benches were used—one 5 feet long (*B*) and the other about 20 inches (*D*, Fig 2). A pair of rugged adjustable tripods (*L*) were used for supporting the optical benches.

For transportation, the entire equipment and a few spare parts were placed in the three cases. The two smaller ones containing the chamber, electrostatic compensator

(*E*), and voltmeter (*V*) were carried by hand throughout the journey, while the large one containing the accessories and 2,000-volt generator was shipped.

(2) Accuracy of Calibration

The accuracy of the compensator depends solely upon the fixed capacity in the compensator case. The calibration of this capacity was checked in each laboratory before it was used. The values of the calibration constant k_0 ,¹⁵ as obtained at the various places, are given in Table I. In addition, a complete calibration of the fixed capacity of the compensator was also carried out in Teddington, giving a value of $828.4 \mu\text{f}$ as compared with $828.2 \mu\text{f}$, obtained before leaving and after returning to Washington. In the final calibration, a variable capacity was used with its series of capacity differences accurate to within 1/10 per cent. No deviation from the mean in any determination exceeded 1/10 per cent.

The voltmeter used for measuring the compensating potential was corrected to 1/10 per cent, a number of checks during the journey indicated that no changes occurred in transit.

Our earlier investigations led to a definite set of requirements which were adhered to as closely as possible in all comparisons. First, a replacement method of measuring the radiation was chosen since it eliminates any uncertainty as to quality variations over the area of the beam, then it is necessary to have the X-ray beam uniform over the area of the chamber diaphragm. Experience has shown that this must be tested for each set-up, visual alignment may lead to error.

Corrections for loss of radiation by absorption in the air between the chamber diaphragm and collector electrode were also

¹⁵ k_0 is the ratio of the potentials V_a/v_0 where v_0 is the potential induced on the insulated system by the application of V_a to the compensator condenser, when all external capacities are removed from the compensator. A determination of k_0 serves as a check on the calibration of the capacity.

considered necessary, though with the guarded field chamber this correction has been reduced to a minimum which is negligible for the highly filtered radiations. With some of the larger air chambers, however, this cannot be neglected anywhere within the practical range of wave lengths

Data for the absorption of heterogeneous radiation in air are very incomplete, hence it was deemed necessary to interpolate between known coefficients for many radiation qualities encountered^{16, 17}. The values in this work so obtained are probably accurate to within about 15 per cent

III COMPARISONS IN THIS COUNTRY

Measurements have been previously described which show an average agreement between the large open air ionization and the earlier guarded field (12 wire) chamber, closer than 0.1 per cent¹⁸. Comparisons between the earlier 12-wire chamber and the present 8-wire chamber showed agreement within 0.2 per cent

In co-operation with Dr G Failla, a comparison of the Bureau's current measur-

would stand transportation. For comparison, the B S compensator was simply connected directly to Failla's calibrated radium ionization chamber. With a steady poten-

It will be noticed that the small differences are progressive, the radium compensator readings becoming more negative with respect to Bureau readings as smaller currents were used.

IV COMPARISON WITH NATIONAL
PHYSICAL LABORATORY

(With the co-operation of Dr G W C
Kaye and Mr W Binks)

The new N P L chamber is of the Duane type with a 10-cm plate spacing. A diagram of the set-up for making the comparison is shown in Figure 3. Their X-ray

Curve I, Figure 4, shows in arbitrary units the distribution of intensity across the X-ray beam as obtained by moving the chamber across it. It should be pointed out that the relative narrowness of such a peak is largely due to the effective slit width of the chamber diaphragm used to "explore" the beam. Some measurements made with a smaller diaphragm indicated a more nearly

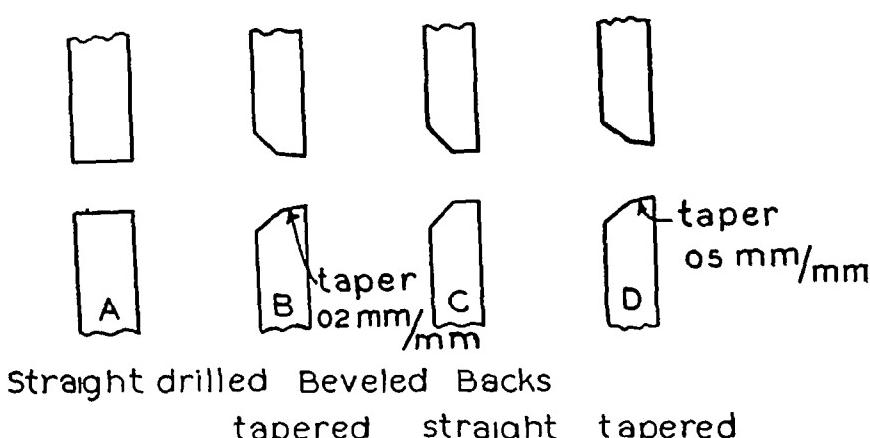

Fig 5 Types of diaphragms used

tube, of the Coolidge deep therapy type, was in a horizontal lead box with a limiting diaphragm (*A*), 12 mm in diameter, at about 40 cm from the target. The ionization chamber diaphragm (*B*) was 8 mm in diameter. The collector electrode (*C*) had a nominal effective length of 8 cm and its center was approximately 35 cm from the diaphragm. They used a null electrostatic compensator to measure the ionization current. Both ionization chambers were mounted on a short cross slide which was, in turn, mounted on a heavy optical bench. (It happened that the Bureau chamber fitted exactly on the N P L track.) The replacement method of observation was used, the two chambers being shifted alternately to position for observation. This distance was so fixed that the front face of the chamber diaphragm was in both cases at the same distance from the target (about 100 centimeters).

uniform distribution. In any case both chambers were very sensitive to alignment. The operating position of the chambers in the beam is indicated by the arrow.

The two compensating systems were separately compared by using them alternately to measure the ionization in the N P L chamber while the X-ray output was maintained constant according to meter readings. In this comparison the B S instrument read 1.47 per cent higher than that of the N P L.

During the comparison of chambers it was found that the chamber diaphragms of the two equipments had different effective areas not accounted for by the difference in their diameters. The N P L diaphragm was about 9 mm thick and the hole was cylindrical (*A*, Fig 5). The B S diaphragm (*B*, Fig 5) had a taper of .02 mm per mm length and was approximately only 4 mm thick along the face of the hole. Depending upon such factors as the focal spot diam-

eter and the distance from target to diaphragm, the two types of diaphragm were found to yield different results. Some measurements made at the same time by the laboratory in Washington, and described below, illustrate this variation.

As dictated by the type of construction, the difference in the distance between the diaphragm and center of the collector for the two chambers amounts to about 15 centimeters, hence the comparatively soft radiation used necessitated corrections for air absorption. These were obtained by interpolation from previous data²⁰.

The final results of the comparisons are summarized in Table III. In giving percentages, the N P L readings are referred as a basis to the guarded field chamber. Runs No 1 and No 2 are straightforward comparisons, Run No 3 was made with the tube diaphragm increased in diameter from 12 to 30 millimeters, and Runs No 4 and No 5 were made with the B S diaphragms on both chambers, hence in this case no diaphragm area corrections of the N P L readings were necessary. This correction for Runs Nos 1-3 amounted to 5.4 per cent as

obtained experimentally. Because of the fact that the diaphragm corrections were unnecessary, the last two runs are probably the most reliable.

The last column, indicating the average deviation from the mean for the observations made with the B S chamber, reveals the effect of the unsteadiness of the X-ray generator, since under the best conditions of operation this average deviation is about ±0.2 per cent.

From these comparisons, we may conclude that the agreement between the chambers alone is probably within the experimental error when using the same diaphragms or correcting for their differences. As the two chambers initially stood, there was a difference of some 9 per cent, which was reduced only by the corrections for air absorption, diaphragms, and compensator differences.

v COMPARISON WITH THE PHYSIKALISCH-TECHNISCHE REICHSDIENSTALT

(With the co-operation of Dr Behnken and Dr Jaeger)

The standard ionization chamber used by the P T R is of the large cylindrical type

²⁰See Footnote 12

described by Behnken²¹ Their X-ray tube is supported vertically in a large lead box (Fig 6) The limiting tube diaphragm is a 3-cm opening in a lead rubber cylinder placed about 5 cm from the tube walls The chamber diaphragm is of the cylindrical type, 7 mm in diameter The collector electrode of the ionization chamber is 30 cm long, with its center approximately 40 cm from the chamber diaphragm A uranium oxide compensator with a null electrometer indicator is used to balance the ionization current²² Their chamber is mounted on a table movable on a track on the floor in a direction parallel to the beam

The B S chamber was mounted on the long optical bench, supported on two tripods, placed at right-angles to the beam and at such a height that the P T R chamber in taking its forward position could pass above it In the operating position the distance from target to chamber diaphragm and the

section of the beam intercepted was the same for both chambers The replacement method of observation was also used here

To check the constancy of the output of the X-ray tube, a thimble chamber was maintained in the beam just off the axis (Fig 6)

The distribution of intensity across the X-ray beam as obtained by the B S chamber is shown in Curve II of Figure 4 The beam is seen to be uniform within experimental limits over a wide area, so that a critical alignment of the chambers was not necessary The working position of both chambers is indicated by the arrows

The diaphragms of the two chambers had the same thickness, so a negligible difference arising therefrom is to be expected This proved to be the case as indicated by some subsequent measurements

The difference in the distances between chamber diaphragm and center of collector for the two chambers was 20 centimeters Comparatively hard radiations, entailing

small air absorption corrections, were used in most of the measurements

The electrostatic and uranium oxide compensators were compared directly in the same manner as with Failla. The results are given in Table IV, referred to the BS compensator as a basis.

The PTR compensator registers a somewhat smaller magnitude than the BS compensator. It will also be noted that the variations are progressive, but in the opposite direction from Failla's. The range of currents in this case is about 1/10 of that used in Failla's laboratory.

The comparison as a whole is given in Table V. The only corrections made were for air absorption in the PTR chamber.

VI COMPARISON WITH FRENCH STANDARD

(At L'Hôpital St. Antoine, with the co-operation of Dr I. Solomon)

At the time of these measurements, the recognized French X-ray standard, measured

in terms of Solomon's unit, was known as the R. This was accomplished with a specific thimble chamber calibrated in terms of the ionization produced by radium under a given set of conditions.²³

Differences in the apparatus, and the general experimental conditions, necessitated a comparison procedure different from that followed with NPL and PTR. A fairly broad X-ray beam was used as a source and measurements made with the two chambers simultaneously in two different parts of the beam. This necessitated placing the Solomon chamber in the beam sufficiently far off the axis so that it did not affect in any way the radiation entering the BS chamber. This position was such that it was impossible to see the thimble chamber when sighting back through the BS diaphragms.

The X-ray tube was placed in a horizontal, oil-filled tank so that the radiation passed through a constant filter of 20 mm

of oil + 10 mm of aluminum. The tube tank was not sufficiently adjustable to provide a horizontal X-ray beam, and, since the B S equipment could not well be used vertically, the beam was brought out at an angle of about 30° with the horizontal. The short optical bench supported by tripods of different heights was inclined at this angle (Fig. 7). The limiting diaphragm was about 3 cm in diameter. The thimble chamber had

an effective length of about 3 cm and was placed 44.5 cm from the X-ray tube target and just off the center of the beam entering the B S chamber. The front diaphragm of the B S chamber was 58.2 cm from the X-ray tube target. As checked later, radiation scattered from the B S chamber did not produce a detectable effect on the thimble chamber readings.

Curve III in Figure 4 shows the distribu-

| Run | K.V | Filter (mm) (+10 Al + 20 mm oil) | Half value layer in copper | r/min BS | R/min Solomon | Corrected for inverse square law | Corrected for leakage | Air absorption correction | Corrected for air absorption | Ratio BS unit/ Sol unit |
|-----|-----|---|----------------------------------|----------|------------------|--|--------------------------|------------------------------|---------------------------------|----------------------------|
| 1 | 110 | 0 | 0.25 | 5.81 | 22.5 | 13.15 | 12.49 | 0.5 per cent | 12.18 | 2.10 |
| 2 | 150 | 0.4 Cu | 0.75 | 3.47 | 14.5 | 8.48 | 8.06 | 1.0 per cent | 7.94 | 2.28 |
| 3 | 190 | 0.5 Cu | 1.0 | 5.85 | 24.8 | 14.50 | 13.77 | 1.5 per cent | 13.63 | 2.29 |
| 4 | 190 | 1.0 Cu | 1.5 | 3.85 | 16.0 | 9.37 | 8.90 | 2.5 per cent | 8.85 | 2.30 |

tion of intensity across the X-ray beam as obtained by the BS chamber. The working positions of both chambers are indicated by the arrows.

Corrections are necessary in this case for the inverse square law and air absorption. The former was applied for the difference in distance of the thimble chamber axis and the front of the BS chamber diaphragm from the target. This required that the readings of the thimble chamber be multiplied by a factor of 0.585. The latter was applied for the distance between thimble chamber and the BS collector electrode—a distance of approximately 26 centimeters. Absorption coefficients were taken from available data. However, as a rough check on these corrections they were also obtained experimentally by moving the thimble chamber in a direction along the beam axis. This could not be done with very great accuracy but the results indicated the corrections used were valid within the experimental limits.

A further correction for temperature and pressure is necessary in this case because the Solomon unit is defined for room temperature. Since the measurements were made at 19°C and 762 mm mercury, a factor of 6.97 per cent was applied to the BS chamber readings. The average deviation from the mean for all the observations was about ± 0.4 per cent.

Table VI gives the results.

It will be noted that for the harder radiation ($HVL = 10$ mm Cu) the Solomon chamber is almost independent of the qual-

ity. However, in going to the softer radiation ($HVL = 0.25$ mm Cu) a change of about 9 per cent apparently takes place. Considering, therefore, only the harder radiation, we find that $1 r = 2.29 R$ as compared with $1 r = 2.2 R$, found earlier by Solomon for the same chamber, which may be counted very good agreement.

As a result of this comparison, Dr Solomon has adopted as his fundamental standard a guarded field ionization chamber identical with that used here.

VII STUDY OF IONIZATION CHAMBER DIAPHRAGMS

(By G Singer, Bureau of Standards)²⁴

The relatively large difference between the effective areas of the chamber diaphragms used by the NPL and BS was unexpected, since earlier ionization measurements at the Bureau of Standards on tapered diaphragms had not indicated any appreciable difference.²⁵ However, if the source of radiation be larger than the diaphragm aperture, some of the radiation incident on the opening strikes the cylindrical wall of the hole in the diaphragm and is effectively cut off (a, Fig. 8). This shifts the effective target-diaphragm position from the outer face toward the inner face of the diaphragm, and

²⁴Washington June 28 1931.

²⁵L S Taylor and G Singer, Bureau of Standards Jour Research (R.P. 169) 1930 IV 631. In reviewing this work it was found that the experimental conditions were not sufficiently like those described above to warrant comparison.

causes an effective shrinking of the diaphragm opening.

The taper diaphragm (*b*, Fig. 8) does not present this difficulty if used far enough from the target to prevent radiation hitting

roughly 12 per cent. The diaphragm *B* was the same as those used on the BS chamber in Europe, having a taper of 0.02 mm per mm on the radius and a thickness of 4 mm up to the bevel. Diaphragm *B*,

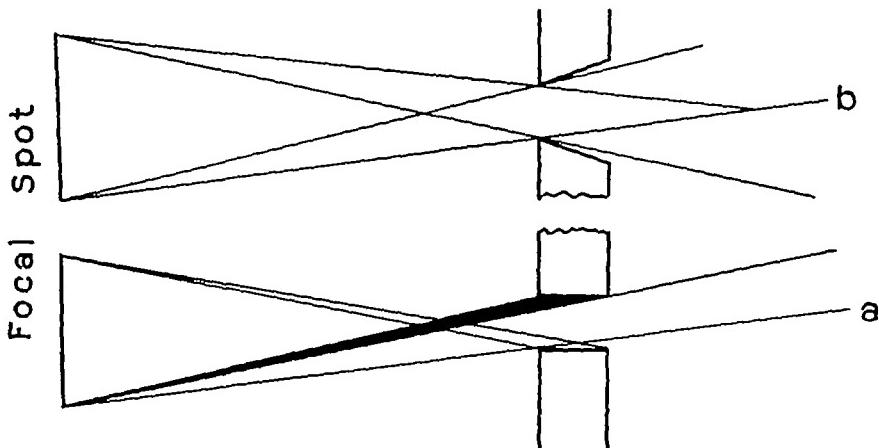

Fig. 8 Effect of thick and tapered diaphragms

the wall of the aperture. It has the disadvantage, however, of introducing arbitrary factors in the diaphragming system. Furthermore, with steep tapers, the front edge of the diaphragm may actually transmit some radiation.

As a result of the discrepancy between the NPL and BS measurements, three carefully constructed diaphragms of the types shown in Figure 5, *A*, *C*, *D*, were compared at the Bureau of Standards. These were used successively on the ionization chamber at a distance of 100 cm from the target and ionization measurements made for the same X-ray output.

The actual measurements of the diaphragms are given in Table VII. Diaphragms *A* and *C* were both drilled and reamed without taper in lead-bismuth plates 10 mm thick, *C* then being beveled off at the back to give a resultant thickness of 4 millimeters.²⁶ From the explanation given above they should differ in transmission by

at a distance of 100 cm from the target, should transmit all the radiation incident on the front of the aperture, and, neglecting transmission through its edges, should pass approximately 0.4 per cent more radiation than the thin straight-walled diaphragm *C*. The diaphragm *D* had about two and one-half times the taper of *B* and was used in these measurements solely to bring out more clearly the effect of the tapered walls.

To compare the effective areas or transmissions of these diaphragms, the volume of air ionized within the chamber is calculated from the measurements of the diaphragm diameter, and from this in turn is determined the ionization per cubic centimeter (I_{cc}) of air.²⁷ I_{cc} is, of course, directly proportional to the effective diaphragm opening. The results are given in Table VIII.

The diaphragm *C* (thin, straight walls) is used as a base in the experimental and calculated values of I_{cc} , both being taken as 100. The agreement between the two sets of

²⁶This type of diaphragm has always been used in previous experiments at the Bureau of Standards.

values is as close as may be expected. It is seen, however, that the difference between A and B is only 1.7 per cent, whereas, at the NPL, the experimentally determined difference between essentially similar diaphragms was apparently 5.4 per cent. A possible cause of this discrepancy may lie in errors in the measurements of the diaphragms as shown below.

The accurate measurement of the diameters of the apertures presented some unexpected difficulties. The BS tapered diaphragms were measured by a method de-

scribed by Failla²⁸ in which an accurately known tapered mandrel was forced a given distance into the lead-bismuth diaphragm. Binks measured two of our diaphragms while we were at Teddington, with a micrometer microscope, and found diameters of 8.005 and 8.035 mm., respectively, whereas, they were both supposed, from mandrel measurements, to be 8.000 millimeters.

To check the reliability of the microscope

or other methods, the diaphragms *A*, *B*, *C*, *D*, in Figure 5, were measured by the Gage Section of the Bureau of Standards,²⁹ using both the micrometer-microscope and plug-gage methods. Diaphragm *B* is the same one measured by Binks. The results given in Table VII show that the micrometer-microscope measurements are consistently larger than the plug-gage measurements. An explanation for this discrepancy is at once obvious from an exaggerated cross-sec-

VIII CONCLUSION — JOINT RECOMMENDATIONS OF THE BUREAU OF STANDARDS, NATIONAL PHYSICAL LABORATORY, AND PHYSIKALISCH-TECHNISCHE REICH-SANSTALT, AND LE SERVICE D'ÉTALONNAGE DE L'HÔPITAL ST ANTOINE

Table IX is given to summarize the results of all the comparisons. The size of the roentgen as measured by each laboratory

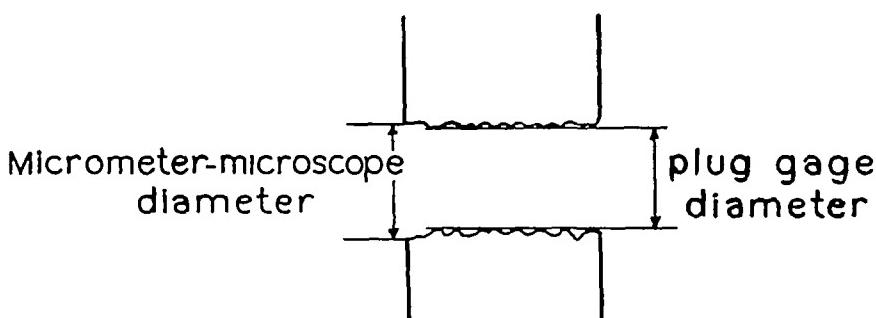

Fig. 9 Magnified cross-section of diaphragm showing where diameter measurements apply

tion of a diaphragm in Figure 9. The microscope method measures only the face diameter of the hole, which is likely to be somewhat beveled or worn in the process of making. The plug-gage, on the other hand, measures the diametral separation between the highest projecting ridges within the bore. The diameters used in the present study were the average from the two sets of measurements and are estimated by the Gage Section to be in error by not more than 1/10 per cent.

It should be mentioned that even when using hard lead it was found impossible to make circular holes. Warping tended invariably to make elliptically shaped openings. As a consequence, the Bureau is discontinuing the use of lead diaphragms and will in the future use a hard gold or lead-calcium alloy the surface of which can be accurately lapped and may be relied upon to hold its dimensions.

²⁹We are indebted to Dr. I. V. Judson and Dr. D. R. Miller of the Bureau of Standards Gage Section for their willing co-operation in this work.

is referred to that measured by the B S chamber as a base

Thus the agreement among the national laboratories is as close as may be reasonably expected and much better than necessary today for practical calibration purposes.

The national laboratories feel justified therefore, in making certain recommendations which should be met by all open-air ionization chambers in order to avoid gross errors. It is believed that these are neither restrictive nor unduly arbitrary. They are

1. The use of an X-ray tube having a focal spot as small as possible (up to 8 mm diameter)

2. The use of a diaphragm placed as close to the tube as possible and having an aperture of such size as to shield from the ionization chamber all radiation except that from the face of the target

3. The use of a standard chamber diaphragm having a minimum thickness but such that not more than 1/10 of the radia-

MEDICO-LEGAL DEPARTMENT

AN IMPORTANT DECISION (WITH SOME PECULIAR ASPECTS)

Roentgen injury during fluoroscopy (Nelson vs Newell (Wis), 217 N.W.R. 723) — This action was brought for malpractice to recover damages from the defendant physician, for alleged negligent and unskillful application of the roentgen rays in such a manner as to produce what was alleged to be a third degree roentgen dermatitis. The alleged injury was the result of diagnostic application (fluoroscopy) of the roentgen rays by the defendant in this case and the subsequent application of the same agent seventeen days later by another radiologist, who, however, was not blamed by the plaintiff, nor included in the action for damages.

The issue was submitted to a jury in the Circuit Court of Racine County (Wis), a verdict was rendered in favor of the plaintiff, and the sum of \$12,500.00 damages was assessed.

Some of the testimony in the case, particularly that of the plaintiff in the case and that of a layman who had been called in as an expert witness, was decidedly fanciful and certainly contrary to established and recognized facts. The testimony of these witnesses unquestionably had considerable weight with the jury and, because the same testimony is quoted in the decision of the Supreme Court, must have had considerable weight with even those learned and erudite jurists.

The case was appealed to the Supreme Court of the State (Wisconsin) and the judgment of the lower court was affirmed. The complete opinion is as follows:

The defendant denies negligence in his answer, and alleged as a defense that the plaintiff was either hypersensitive to the X-ray, or that the burn was due to the cumulative effect of the X-ray, in an examination made by another doctor about seventeen days

subsequent to the X-ray examination by the defendant. The object of an X-ray examination and the manner of the operation of the machine are quite generally known, and have been described to a considerable degree in detail in the cases involving malpractice of physicians based on the X-ray examination or treatment, so that no further explanation herein will be attempted.

On the morning of May 10, 1924, the plaintiff called at the defendant's office in order to ascertain, by the use of a fluoroscope, the cause of his apparent ill health. He was subjected to two examinations, one in the morning between the hours of 9 and 10 and one in the afternoon of the same day. The defendant testified that in the use of the fluoroscope he applied the usual and standard dose for the purposes of an examination. Plaintiff testified that after the second examination he experienced, while returning to his home, an itching sensation in the small of his back, which became more aggravated from that time until the fourth or fifth day thereafter, at which time the place where the X-ray was applied manifested an area of redness in the form of an oblong, that the itching thereafter continued, and that, seventeen days after this examination by the defendant, he called at the office of one Dr Fortier, an X-ray specialist, of Milwaukee, where three X-ray pictures were taken, the X-ray being applied to the front of his body. Dr Fortier was not informed at that time of the examinations made by the defendant.

On or about October 1, 1924, it became apparent that the plaintiff suffered from ulcers in the region of his back where the defendant applied the X-ray, and it is undisputed in the case that the ulcers so appearing manifested a third degree burn. There is also testimony that the ordinary and usual application of the X-ray for purposes of a fluoroscopic examination consists of a dose equivalent to 1/20 of

what is known as an erythema dose, and that an erythema dose is sufficient to create an area of redness at or around the place where the X-ray is applied. Defendant's experts testified that they had never heard of a manifestation of itching within several hours of the examination, that it occurred as a rule between 10 and 12 days after the examination, that an appearance of redness 4 or 5 days after the examination is also unusual.

In many of the cases of malpractice in which it is charged that the physician had caused the injury by the negligent use of the radiograph in fluoroscopic examinations, or by an overdose of the X-ray, or by the application of the X-ray for an excessive length of time, the defense is interposed, as in the instant case, that the patient is abnormal and hypersensitive to the X-ray treatment, and this defense has proved itself quite generally successful. It also appears in the evidence that no method has been discovered by means of which it can be determined if a given subject is hypersensitive to the X-ray. It is undisputed that cases of hypersensitivity are extremely rare, that an X-ray burn of the third degree constitutes a serious injury, and may result in permanent injury, that a third degree burn caused by an X-ray destroys the skin and the deeper tissues of the body and also the blood vessels, and that an operation or operations connected with such an injury are extremely painful.

Dr Dorr, one of the defendant's experts, testified that he had performed in the neighborhood of 10,000 X-ray examinations of the chest, and numerous other examinations with respect to other parts of the body, that he had in many instances applied the ordinary X-ray doses to infants within an hour after their birth, and that he had never in his practice produced a third degree X-ray burn. Dr Epperson, also a witness for the defense, confirmed as to his practice Dr Dorr's experience, but his practice covered in the neighborhood of 25,000 cases. Dr Perry, the expert for the plaintiff, testified that after an examination of the plaintiff's back shortly before the trial, he was convinced that the injury constituted a third degree X-ray burn. A hypothetical

question put by counsel to Dr Perry, including substantially all of the facts shown in the evidence, elicited the answer that he knew that the burn was caused by an excessive or improper application of the X-ray, and that in his opinion the injury resulted therefrom.

The ordinary and standard dose, according to the testimony of the defendant, was applied in the instant case. Such a dose consists of 1/20 of an erythema dose. Dr Perry also testified that in order to produce a third degree burn it would be necessary to use at least one and one-half or double an erythema dose. The jury had a right to believe this testimony of Dr Perry, and, assuming it to be true, it will become apparent even to the mind of a layman that the use of the standard dose for examination purposes leaves an enormous factor for safety.

Absolute certainty that the injury resulted from negligence is not required in the law. Even in criminal cases, the rule is that, where a jury is satisfied beyond a reasonable doubt, the verdict of the jury will not be disturbed. In civil cases, the rule requires proof which satisfies the mind of the jury to a reasonable certainty. In this connection, therefore, if we consider the testimony of the defendant's experts, Dr Dorr and Dr Epperson, and in view of all of the other testimony in the case, the overwhelming probability supports the finding of the jury herein and the judgment of the court.

If a verdict such as was rendered in the instant case upon the evidence adduced therein can be set aside upon the ground of a mere speculation that the subject is one who possesses a hypersensitivity to the X-ray, then it might be admitted that cases of this kind cannot be successfully prosecuted. The use of the X-ray in a physician's practice in modern times has become almost indispensable. Its importance cannot be overestimated. It is used in connection with all classes of injuries and it proved of inestimable value to mankind during the recent war. The X-ray apparatus has been improved from the time of its invention, so that it has now acquired not only a remarkable degree of efficiency, but also of reliability. But, conceding the tre-

mendous value of the X-ray, it must also be admitted that the improper and negligent use thereof may result in injuries and suffering which are appalling, and notwithstanding the efficacy of this remedy, the welfare of mankind requires that a physician who operates an X-ray machine is under duty to exercise a degree of care, diligence, judgment, and skill which physicians in good standing in the same school of medicine usually exercise in the same or similar localities under like circumstances, having regard to the advanced state of medical and surgical science at the time the physician discharges his legal duty to the patient *Kuehnemann vs Boyd (Wis.)*, 214 N W R 326

Seventeen days after plaintiff's visit to the defendant, he had three X-ray pictures taken by Dr Fortier, of Milwaukee. It is claimed that the injury results from the cumulative effect of the X-ray. The testimony shows that the ray applied in Dr Fortier's office was merely for examination purposes, and not for treatment, and that it was applied on the front of his body, while the patient (plaintiff) was reclining. Mr McIntosh testified in general that there is a possibility for an X-ray burn to appear on the back, where the ray is applied in the front, but that ordinarily the burn would make itself manifest at the point of application of the ray.

In this case it appeared that the itching sensation was manifested about two hours after the final treatment by the defendant, while ordinarily such a manifestation does not occur before 10 or 12 days thereafter. It continued for a long period thereafter, and became more aggravated as time went on. Furthermore, the redness of the skin appeared between four and five days after the visit to the defendant, and it appears that such a manifestation ordinarily does not appear before the expiration of from ten days to two weeks. This, in connection with the testimony of defendant's expert, McIntosh, that the burn ordinarily appears at the point where the X-ray enters the body, and the opinion evidence of Dr Perry, plaintiff's expert, establishes the basis for a logical conclusion that the burn

resulted from the negligent application of the X-ray by the defendant.

Defendant's counsel assign as error the giving by the court of the following instruction:

"You are instructed that the fact that a bad result following the treatment, if you find such was the fact from a consideration of all the credible evidence in the case, is not alone sufficient to charge the defendant with negligence. You are therefore not at liberty to conclude that the defendant was guilty of negligence or malpractice from the mere fact that bad results follow the treatment, *although that fact may be considered, together with all the other evidence, in reaching your conclusion*. The defendant cannot be held liable unless you are satisfied by a preponderance of all the credible evidence in the case, to a reasonable certainty, that he failed to use that skill and care which I have already mentioned and instructed you it was his duty and obligation to exercise in his treatment of the plaintiff and that such failure to exercise such care, if you find that he so failed, proximately caused injuries to the plaintiff."

That this instruction constituted error appears from the holdings of this court in the cases of *Kuehnemann vs Boyd (Wis.)*, 214 N W R 326, and *Rost vs Roberts*, 180 Wis., 207, 192 N W R 38. We do not consider this case as a close one, and therefore conclude that the error is not prejudicial, under the provisions of the Statutes.

Error is also assigned upon the ground that the damages awarded are excessive. We have carefully reviewed the evidence, and in view of the actual loss of time, the seriousness of the injury, and the pain and suffering of the plaintiff, we are satisfied that the amount awarded is supported by the evidence.

OTHER CASES REPORTED

Slander of Physician (Amick vs Montross (Iowa), 220 N H R 51) — The plaintiff, a licensed physician, sued the defendant for slander. He alleged, among other things, that the defendant maliciously and untruthfully said to Dr M in the presence of Dr S, "I heard Doc A was drunk that night and wasn't able to go, was the reason

you were called" This statement was made, the plaintiff asserted, in connection with a confinement case, for the purpose of injuring his business and reputation On motion of the defendant, the statement was withdrawn from consideration by the jury, on the theory that it was not actionable *per se* (that is, in and of itself and without proof of actual damage) and that on the entire record there was nothing, so far as this charge was concerned, to be submitted to the jury From a decision in the trial court, the plaintiff appealed to the Supreme Court of Iowa He contended that the language stated was actionable *per se*, because it charged him with drunkenness, and drunkenness was a crime, and also because the language was prejudicial to him in his profession The Supreme Court concluded that, under the laws of Iowa, drunkenness was not such a crime as would make an allegation of drunkenness against a person actionable *per se* The court held, however, that the language used by the defendant was prejudicial to the plaintiff in his profession and for that reason was actionable *per se* It is true, said the Court, that the language used does not charge the plaintiff with any lack of professional knowledge or skill, or misconduct in the plaintiff's professional capacity, or any impropriety in treatment It does charge, however, in substance, that at a time when a doctor was needed the plaintiff was drunk and unable to render medical service and attention Said the Court

A lawyer, a banker, a merchant, and men engaged in many other occupations have regular business hours A physician's occupation differs therefrom Sickness and accidents occur at any hour of the day or night The emergency may happen at any minute, when the services of a doctor will be needed The doctor is engaged in the practice of his profession every hour of the day To say of a physician, in substance, that he was drunk and unable to attend upon a call, reflects upon his

professional character One would not be likely to call a doctor in case of sickness, accident, or emergency if there were any probable cause for believing that he would be found in a state of drunkenness Such a charge "necessarily must, or presumably will as its natural and proximate consequence, occasion him pecuniary loss"

The Supreme Court held, therefore, that as there was sufficient evidence to prove the making of the statement complained of, the trial court was in error in withdrawing it from the jury

The defendant pleaded in mitigation of the damages the general bad reputation of the plaintiff, as a physician and surgeon and doctor in the town of M_____ and vicinity Over the plaintiff's objection, he was allowed to introduce evidence to support this plea The plaintiff, on appeal, contended that this was error, because the language complained of was uttered by the defendant, at N____E____, and the evidence adduced by the defendant should have been limited to evidence of the plaintiff's general reputation in that community It appeared, however, that the distance between the two communities was only eight miles The evidence received, said the court, was in exact conformity with the defendant's plea of mitigation and was properly admitted

Because the trial court withdrew from the jury that count in the plaintiff's complaint based on the charge of drunkenness, the judgment of the court below was reversed and the cause remanded

Ethics Collusion between Physician and Lawyer Justifying Disbarment (In re Burke (N.Y.), 237 N.Y.S. 53)—In order to secure payment of his bills for professional services a physician recommended personal injury cases to a lawyer Payment in such cases was contingent on the results This arrangement violated the ethics of the legal and medical professions and was likely to lead to false testimony as to the nature of

the injuries. The lawyer was suspended from practice for two years.

Opinion Based on Absent Roentgenogram is Inadmissible as Evidence (People vs Williams (Ill.), 169 N.E.R. 190)—In a prosecution for murder, a coroner's physician testified that he examined the body after death, that a roentgenogram showed that the bullet passed from the left to the right side of the body, shattering the ninth rib and the spinal cord, and that he viewed the body only and took the records from the hospital, but made no autopsy. He admitted that there was doubt as to the cause of death, but he stated that in his opinion death was due to heart disease, superinduced by nephritis, an infection of the kidneys, and an inflammation of the bladder, due primarily to the cutting of the spinal cord by the gunshot wound. No objection was made to the admission of this testimony when it was offered. On cross-examination, however, when the witness admitted that he had made no postmortem examination of the body and that he obtained his information as to the cause of death from the records of the hospital, counsel for the defendant moved to strike out his testimony with reference to the cause of death. The court did not rule directly on the motion but said that the witness might testify as to what he saw and remembered about the roentgenogram, which was "simply a physical thing." The roentgenogram was not introduced in evidence nor in any way identified, nor did the witness qualify as an expert in the reading of roentgenograms. The defendant was convicted and thereupon appealed to the Supreme Court of Illinois.

The testimony of the coroner's physician, said the Supreme Court, when given from the records of a hospital without proof of their authenticity, was clearly inadmissible as hearsay, and should have been stricken out. His testimony concerning matters disclosed by the roentgenogram was likewise inadmissible because no ground had been

laid for such testimony. The rule in regard to the use of roentgenograms, when it is sought to put them in evidence, requires that the witness testify either that the roentgenogram shows accurately what the witness saw by examining the body through a fluoroscope, or that the witness is skilled in the use of the roentgen machine, that he took the roentgenogram concerning which he testifies, and that he is able to say that it is accurate. It was clearly error to permit the witness to testify, giving his conclusions as to what the roentgenogram showed, without proof of his qualifications and of the accuracy of the roentgenogram, and without accounting for failure to produce it. There was no proof of the cause of death, other than the testimony of this witness. As such proof rested on incompetent testimony, its admission was an error requiring the reversal of the judgment.

Workmen's Compensation Acts Liability of Physician for Malpractice (McDonough vs National Hospital Assn (Ore.), 294 P.R. 351)—The Oregon workmen's compensation act provides that a workman injured in the course of his employment by the negligence or fault of a third party has a choice of remedies. He may proceed under the statute to obtain an award of compensation or he may proceed against the third party at common law, but he cannot do both. Having pursued one remedy, he is barred from subsequently invoking the other, if he elects to take under the act, he must assign his cause of action against the third party to the commission, for the benefit of the accident fund. An aggravation of the primary injury resulting from the mistake, negligence, or malpractice of a physician in treating the original injury is compensable under the act. Once having received and accepted compensation for the combined injuries, the employee cannot maintain an action against the physician for malpractice.

Libel Report of Examining Physicians Appointed by Court (Mickens vs Davis (Kan.), 294 P R 896)—The written report of physicians appointed by a court to make a physical examination of a party to an action in that court constitutes a privileged communication and cannot be made the basis for an action for damages for libel. In this case the plaintiff had obtained a judgment in the District Court of Douglas County against his employer under the workmen's compensation act of Kansas. Subsequently the District Court appointed the defendants, physicians and surgeons, to examine the plaintiff to determine whether his disability was still existing and whether it was permanent or partial. They were instructed to report the result of their examination to the court. The defendants reported, among other things, "that the cause of plaintiff's injury was a spinal lesion apparently due to syphilis, and that same was a progressive lesion, and that he, the plaintiff, would probably never be better than he is now."

Thereupon the plaintiff sued the defendants for libel. The Supreme Court of Kansas held that the report was privileged and that the plaintiff could not base an action for libel on it.

Chiropractic Treatment must be Limited to Manipulation (Heintze vs New Jersey State Board of Medical Examiners (N J), 153 Atl R 253)—The appellant, Heintze, was licensed to practise chiropractic in New Jersey under Chapter 4, Laws of 1920, which apparently authorized chiropractors to treat human ailments by manipulation only.

Heintze, however, used a vibrator, an electric light, and the galvanic current. His assistant, in his presence, gave directions for a vegetarian diet and the use of flaxseed tea. "That such practice does not constitute the practice of chiropractic," said the Supreme Court of New Jersey, "but does constitute the practice of medicine and surgery, seems entirely plain." The Medical Practice Act of New Jersey is not unconstitutional because it provides for a trial without a jury of persons charged with practising medicine and surgery without licenses. The judgment of the trial court, convicting Heintze of practising medicine and surgery without a license, was affirmed.

Note—Here is a fine decision for our New Jersey colleagues at least and for physiotherapists in general. *Diet, radiation, and electric treatment constitute the practice of medicine*

CASE REPORTS AND NEW DEVICES

A CASE OF PULMONARY FIBROSIS OF OBSCURE ETIOLOGY, WITH BILATERAL SPONTANEOUS PNEUMOTHORAX¹

By MAJOR ALBERT BOWEN, MC, U S A,
HONOLULU, T H

This is a rather unusual case which has considerable interest from the viewpoint of roentgen diagnosis and as a curiosity presenting multiple, bilateral, spontaneous pneumothoraces with absorption and apparent cessation of the latter.

The patient, C S, aged 25 years, enlisted in the Army in March, 1925. For a short time he worked in an open stone quarry. In May, 1925, he began to have diarrhea with from 10 to 20 bloody stools a day, which has continued with slight occasional improvement up to the present. Soon after the onset of the colitis, he began to have pain in the chest, with productive cough and shortness of breath. In addition, he had pain and soreness in the lower abdomen, fever up to 102°, chills, with night sweats, and loss of weight. Later, he developed skin lesions which were shallow, indolent ulcers with much itching and secondary infection due to scratching. The patient was treated in the local station hospital before being sent to Walter Reed General Hospital for study and treatment.

Examination at the latter hospital showed a flat chest, with abdominal breathing, some dullness and fine as well as coarse, moist râles over the entire chest persisting after coughing. The lower abdomen was tender. There were internal and external hemorrhoids.

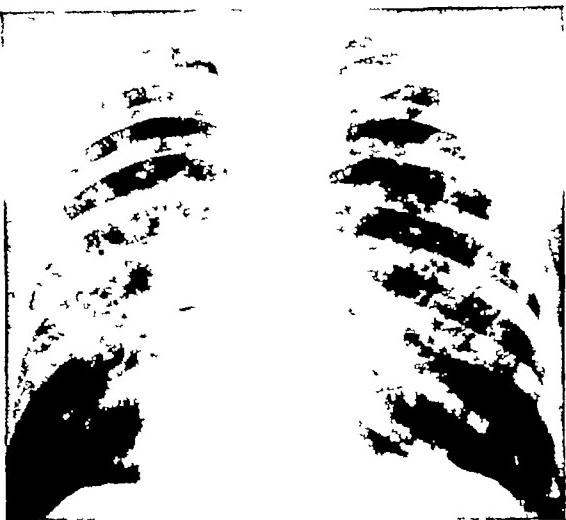

Fig 1 Before pneumothorax, showing extensive interstitial fibrosis

X-ray examination of the chest showed that in both lungs, from the first to the fifth ribs, anteriorly, there was a fine mottling, symmetrically distributed. Linear markings were thickened and the hilus shadows were prominent. The impression was of probable pneumonoconiosis, with tuberculosis to be considered. The gastro-intestinal series was essentially negative.

Sigmoidoscopic examination showed many superficial ulcers, with submucosal hemorrhages extending down to the rectum. Diagnosis was ulcerative colitis.

Sinus examination showed positive maxillary antra, which were treated. There was much dental work done to clean up the mouth and the tonsils were removed. Examinations for tubercle bacilli and parasites were consistently negative.

The patient showed some improvement and gained ten pounds during a stay of fourteen months at Walter Reed Hospital. Among the many things tried he was treat-

¹Published with the consent of the Surgeon General of the Army who assumes no responsibility for any statement contained therein.

Fig 2. After spontaneous pneumothorax on the right side.

Fig 3. Bilateral pneumothorax, more extensive on the left side.

ed by emetin and vaccines, but no form of treatment helped very much.

He was discharged from the Army for disability, later going to the Soldiers' Home Hospital. In 1928, he went to New Mexico, where he tried to work, but, becoming worse again, he returned to the Soldiers' Home.

In November, 1930, he was transferred to Fitzsimons General Hospital for observation for tuberculous enteritis. On admission, the patient was having from ten to fifteen bowel movements a day, some pain in the chest, but no cough or sputum. At this time, the fingers were clubbed, there were healing furuncles on the right shoulder, and the chest had râles and increased dullness to percussion. X-ray examination (Fig 1) showed very heavy, bilateral, interstitial fibrosis, with some emphysema at the peripheries. Laboratory studies from stools, sputum, and scrapings from ulcers were negative for tuberculosis, fungi and parasites. A course of potassium iodide produced no change in the patient's condition.

On Jan 15, 1931, the patient had sudden pain in the right chest with a feeling of full-

ness, but not much embarrassment. X-ray examination showed a moderate pneumothorax on the right side, with emphysematous blebs on the periphery. It was believed that a bleb had ruptured and that the fibrosed lung had prevented complete collapse (Fig 2). February 5, following a severe coughing spell, the patient had pain in the left chest, cyanosis, and shortness of breath. Three hundred c.c. of air were drawn off. X-ray examination showed bilateral pneumothorax (Fig 3). On February 17, there was another similar attack on the right side, and X-ray films showed an increase in the pneumothorax. At this time, 200 c.c. of air were withdrawn. On March 3, there was sharp sudden pain on the left side, with dyspnea and cyanosis. X-ray examination showed an increase of air in the left lung. X-ray films made on March 8 showed some fluid and pleurisy on the left side. On March 22, there was acute pain in the left chest, respiratory embarrassment, heart to right. One thousand c.c. of air were withdrawn. Another spontaneous pneumothorax occurred on the right side on April 3 but with fewer symptoms. Spon-

Spontaneous pneumothorax occurred on the left side on April 28, accompanied by less severe symptoms.

That the patient did not develop empyema with these many lung ruptures is probably due to the fact that the ruptures were at the extreme periphery, distant from large bronchi.

The emphysematous blebs contained little or no fluid and did not discharge infected material into the pleura. Although the blebs collapsed, the point of rupture remained like a valve and probably continued to force air into the pleura for several days, when there was coughing or forced inspiration. This may account for the delay in absorption of the air.

Later chest examinations showed the air being absorbed in both sides, with considerable pleural reaction. Both lungs gradually re-expanded and the patient has since had no more spontaneous pneumothoraces. It is believed that generalized pleural adhesions formed which hold the lung to the parietal pleura and prevent rupture of the blebs and collapse. The fibrosis has gradually increased.

Repeated microscopic and cultural studies of scrapings from ulcers on skin and sigmoid and of sputum continued to be negative except for two different fungous growths which were believed to be air contaminations.

On Sept 16, 1931, the patient left the hospital, his condition not much changed from that found on admission. The diagnosis was (1) Colitis, chronic, ulcerative, cause undetermined, (2) Interstitial fibrosis of both lungs cause undetermined, (3) Multiple, spontaneous, bilateral pneumothorax, due to the fibrosis.

We shall be glad to receive comments on the etiology from any who have had similar cases. Our impression is that it is of mycotic origin in spite of the continued negative findings.

THE RADIOGRAPHIC DETECTION OF THE CATFISH SPUR AS A FOREIGN BODY

By ROBERT B TAFT, M.D., B.S.,
CHARLESTON, S.C.

Some time ago I was asked to attempt the radiographic determination of a foreign body of a rather unusual nature. This foreign body was supposed to have been the spur of a catfish.¹ Being unfamiliar with the composition of this spur, I secured one and was rather surprised to find it dense enough to cast an excellent shadow through the flesh or bones of a man's foot. As the wounds from this fish are of frequent occurrence in this region, I felt that the matter might be of some interest.

The catfish is often caught by those who fish along the beaches of the South Carolina coast and since it is not regarded as edible except by the colored people, it is felt to be a nuisance and is left to die on the shore, where it is frequently stepped upon. The

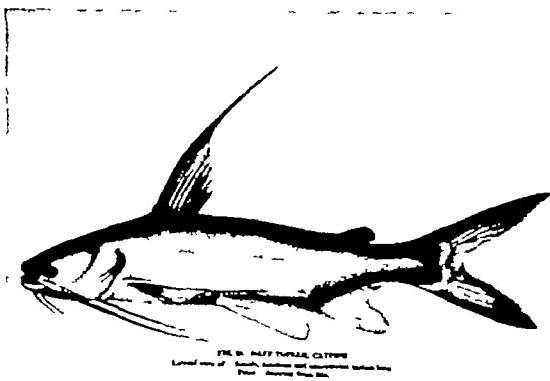

Fig 1. The sea catfish, copied from an illustration by Gruber, "Zoologica," Vol II, No 5

¹This is a summary of the article which appeared in "Zoologica," August, 1916. "The Gaff Topsail A Sea Catfish that Carries its Eggs in its Mouth." The Gaff Topsail Catfish (*Felichthys felis*) is a subtropical form ranging as far north as Cape Cod but is especially common along the coasts of Florida and the Indian River. From Thomas Ash's "Carolina" comes the following description of it: "Catfish whose head and glaring eyes resemble a Cat; it's esteemed a very good fish, it hath a sharp thorny Bone on its Back, which strikes at such as endeavor to take it; which by seamen is held venomous. The male incubates the eggs in his mouth not only until they are hatched but until the young are able to take care of themselves. The largest number taken from the mouth of one male was 55."

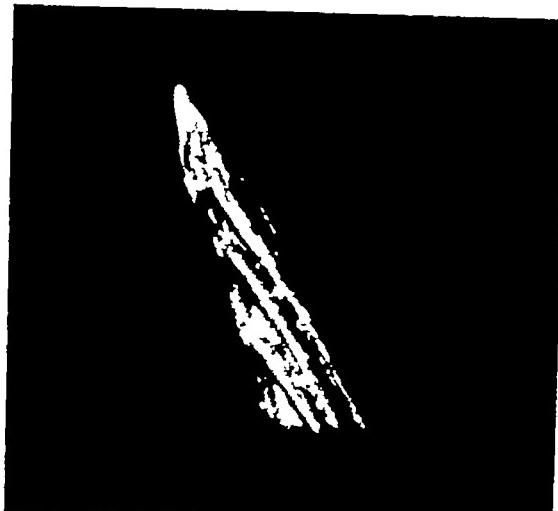

Fig 2 The spur of the catfish magnified about 20 diameters

Fig 3 The spur superimposed on an adult foot showing the density. The actual fragment reported in this paper is too small to permit of reproduction in an illustration

spur (Figs 1 and 2) has a number of barbs which make it very difficult of withdrawal from the wound and there is some chance that small fragments may be broken off. While it is commonly believed that the slime from this fish is poisonous, there is no real foundation to that idea, but at least the wound gives pain out of all proportion to a clean wound.

In this particular instance a woman stepped on a catfish which had been recently caught. The spur penetrated through the sole of her shoe, obliquely through the second toe, and into the great toe. The spur was examined by some one in the party and pronounced whole but it is doubtful if the examination was very carefully made.

For about five days the patient was able to walk, but with difficulty, following which the pain became so severe that she had to remain in bed for a week. Discharge continued from the wound for about one month.

A radiographic examination made about two weeks after the injury showed a minute foreign body in the soft tissue of the great toe, just medial to the base of the proximal phalanx. This body, which was triangular in shape, was seen in the same position on five

films of different densities. It seems reasonable to believe that this was the point of the spur. No attempt was made to remove the fragment, as it could hardly have been found. Another series of films made two months later showed that it had disappeared, either by discharge from the wound or absorption. This piece of spur was so small that it could not be reproduced in a magazine illustration, so a similar spur was procured, placed beneath a foot, and a test film made. This spur which is shown in Figure 3, is seen to be quite dense, showing well through the metatarsal bones.

This case is reported because, so far as I know, no mention has been made of a similar one in any previous writings.

I am indebted to Mr E Milby Burton, Acting Director of the Charleston Museum, for the information about this fish.

LYMPHOBLASTOMA AND TEMPERATURE IN IRRADIATED PATIENTS

By JAMES R. GEMMILL, M.D.,
MONESSEN, PENNSYLVANIA

The following is a study of patients having lymphoblastoma who were admitted to

the Massachusetts General Hospital for irradiation. The effect of irradiation upon the temperature is noted and what part the enlarged liver, when present, contributes toward increased temperature. This study

The temperature range showed no relation to the amount of involvement, being high in cases with but one group of nodules and evidencing a moderate increase, or none, when the glands showed marked extension

Massachusetts General Hospital

NAME E R

DISEASE Lymphoblastoma

DATE May 24

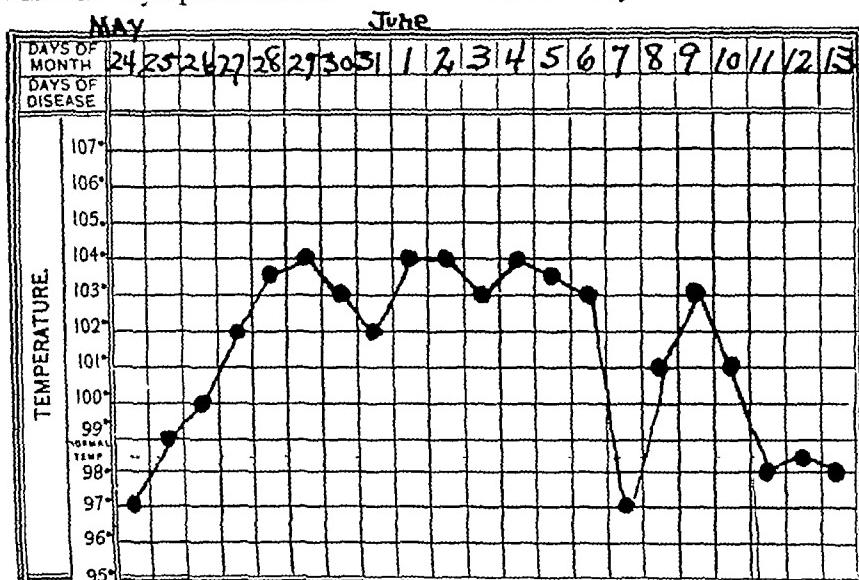

Chart I Temperature range during the time in which the patient was not subjected to irradiation

comprises a group of 73 cases of lymphoblastoma, all of which were proved by biopsy.

Rise in temperature in lymphoblastoma is thought to be due to areas of necrosis which have been observed at autopsy in the glands affected, though many cases having high temperature during the course of the disease and coming to autopsy show no necrosis. The areas involved as shown clinically were the cervical, axillary, and inguinal lymph nodes, the spleen and the liver. In some patients but one group of glands was affected, others showed two or more affected groups at the same time.

of the process. The temperature curve was notably out of proportion to the physical findings. In cases which showed enlargement of the liver the reaction of the temperature was identical with involvement elsewhere. Irradiation with high voltage X-ray was given over the areas involved by the process, the dose being calculated as suitable for the individual and producing improvement in the condition present. Temperature of varying heights was noted at the beginning of the application of irradiation showing no reaction with relation to the time or number of treatments though the patients improved both physically and

**MASSACHUSETTS GENERAL HOSPITAL
(SURGICAL CHART)**

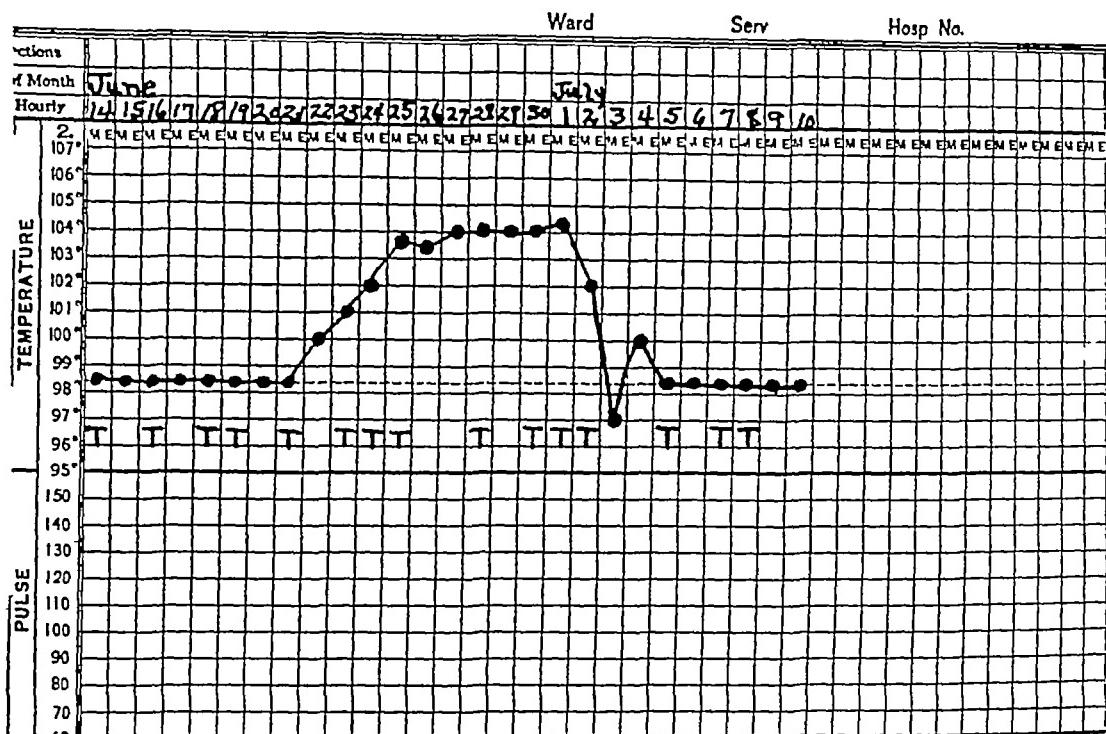

Chart II Temperature range during X-ray treatment "T" indicates days on which the treatment was given

TABLE I
Temperature

| Types | Pel-Ebstein | Prolonged | Slight or None |
|---------------------|-------------|-----------|----------------|
| Lymphoblastoma (21) | 4 | 10 | 7 |
| Pseudoleukemia (25) | 5 | 10 | 10 |
| Lymphoblast (21) | 3 | 8 | 10 |
| Lymphosarcoma (6) | 0 | 0 | 6 |

clinically. A few patients showed a reaction to the effect of the X-rays immediately after treatment, evidenced by nausea and chilling. The temperature remained unchanged.

Baldridge and Awe,¹ in their studies of the incidence of temperature in lymphoma, grouped their cases according to the histo-

logic picture and types of temperature. In a similar manner I have grouped the cases of lymphoblastoma (Table I).

Pel-Ebstein is the name given to a remittent and intermittent type of temperature which rises and remains high for from three to thirty days, and does not show a septic character. The following is a case of this type showing the course of temperature prior to irradiation and the absence of reaction to its effect.

Case 1 A housemaid, single, white, native-born, aged 28 years, entered the hospital complaining of swollen glands on both sides of the neck. Her history included influenza, followed by pneumonia twelve years previous to the present examination, tonsillectomy, and adenoidectomy eight months previous to the present exam-

¹C. W. Baldridge and C. D. Awe. Arch. Int. Med. February 1930. XLV. 161-190

ination, after several attacks of severe sore throat. For a year and a half the patient had noted a feeling of weakness, with gradual loss of weight and alternate swelling and recession of the glands in the neck, the condition being more marked during the seven months preceding examination, accompanied by rise of temperature from 101 to 102 degrees F.

Physical examination showed the cervical glands to be the size of marbles, the spleen palpable, and a palpable mass present near the iliac crest on the right side.

The X-ray examination showed the hilus shadows on both sides to be increased in width and density, with sharply lobulated borders.

The patient was admitted on May 24, 1930. The temperature range from the day of admission until June 11, 1930, during which time she was not subjected to irradiation, is shown on Chart I. On June 14, treatment by irradiation was instituted, the areas treated being the right and left side of the neck, spleen, and anterior and posterior chest. Approximately 525 r units of high voltage X-ray were given over each area in divided doses.

DISCUSSION

All the patients included in this study were admitted to the Massachusetts General Hospital during the period from 1925 to 1931.

Only those cases proved by biopsy to be lymphoblastoma are included in the group.

All the patients received high voltage X-ray treatment while in the hospital and showed improvement to some degree, either symptomatically or clinically.

The temperature curve failed to show any change concomitant with the changes in the involved areas or the application of irradiation.

CONCLUSIONS

1 Irradiation exerts a beneficial influence upon the process of lymphoblastoma although it fails to bring about any change in the various types of pyrexia.

2 The enlargement and recession of the liver and the rise and decline of temperature pursue courses, each without relation to the other, and they are not dependent upon the changes in the general progress of the disease.

ANOMALY OF THE HEPATIC FLEXURE OF THE COLON REPORT OF CASE

By WALTER WASSON, M.D., and JOHN S. BOUSLOG, M.D., DENVER

Anomalies of the hepatic flexure of the colon are not as common as the wealth of literature on the subject would lead one to expect. The one which we wish to present is of a kind recognized by various names, but most descriptively termed (by the Continental authors) "hepato-diaphragmatic interposition of the colon" (1, 2, and 7).

There is a type of redundant colon which shows this same interposition of the colon between the diaphragm and the liver, and which may be permanent or temporary (2, 3). Whether the condition is due to increased length and consequent overlapping or just to malposition, it is undoubtedly anomalous. The etiology is to be found in defective embryological development (2).

The condition was first described roentgenographically in 1899 by Béclère (4), and quoted by Tremolières and Pierron (7) and Just (2), but Curschmann (5) described it fully in 1894 in his classic monograph on the subject. In 1920, Swezey and Black (6) reported a similar case which was detected by one of us in the diagnosis of routine chest roentgenograms. At that time, only one other case could be found. A review of the

logic conditions as malignancy of the cervix and uterus and the benign metrorrhagias, there has not, until now, appeared any specially contrived instrument to facilitate the handling and insertion of these tubes in the uterine canal. Workers with radium have long felt the need of a forceps so constructed that cylindrical tubes, either of metal or rubber, may be readily picked up,

firmly grasped, and easily directed into the cervical or uterine canal. Heretofore, the ordinary curved dressing, straight billed, or placental forceps were employed for this purpose, but none of these held the radium tubes firmly or prevented slipping or rotation, especially when a lubricant had been used on the tube. Moreover, in those cases in which fixation of the cervix is marked,

Most authors agree that the therapy should follow the same lines as that for visceroptosis, and that surgical relief is to be considered only as a last resort

with probable adhesions in the region of the liver, but without any obstruction

COMMENT

CASE REPORT

Mrs E W, white, widow, aged 57 years, was referred to us for gastro-intestinal examination, in February, 1930. She complained of pain in the right upper quadrant, and was annoyed by gas and constipation. The latter responded to laxatives.

Previous History—She had had an appendectomy twenty-five years previous to the present examination. Two years after the appendectomy she passed some kidney stones, had a bladder infection, and was operated upon for a kidney suspension. She also had had an operation for some uterine disorder.

Six or seven years before she was referred to us, she began to have pain in the right side of the abdomen, gas, constipation, pain and indigestion associated with meals.

Present Condition—The patient was a tall, flabby looking woman, whose average weight was 128 pounds. Her general condition seemed fair. She was especially tender over the right abdomen, but no mass was palpable.

Roentgen Examination—Roentgenographically, we found that the gall bladder filled and emptied well. The stomach was poor in tone, and emptied in 6 hours. The pylorus was negative, the duodenum swung to the right, and the first portion turned downward. This was a most unusual position, but there was no definite pathology revealed. The small intestine swung well toward the region of the gall bladder, but there was no obstruction. The cecum was low and large. The hepatic flexure lay beneath the diaphragm, and there was considerable stasis. The roentgen diagnosis was anomaly of the hepatic flexure of the colon,

This case of anomaly of the hepatic flexure of the colon is important in that the anomaly was an interposition of the colon between the liver and the diaphragm. There was considerable stasis of the colon, with toxic symptoms. The inverted position of the duodenum was also unusual. The value of the roentgenographic examination lay in that it demonstrated the fallacy of considering operation to relieve the bowel condition in the right lower quadrant.

UTERINE INTUBATOR, A NEW TYPE FORCEPS

By HYMAN I TEPPERSON M.D., Attending Radiation Therapist, Brownsville and East New York Hospital, Associate Radiation Therapist, Brooklyn Cancer Institute (Ira I Kaplan, M.D., Director), BROOKLYN, NEW YORK

Although radium tubes have been used extensively in the treatment of such gyneco-

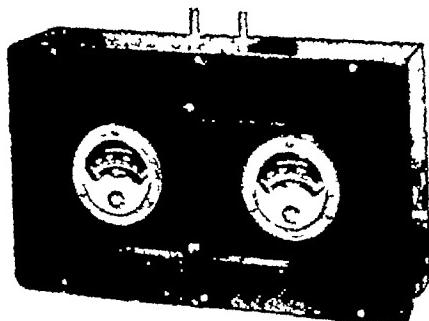

Fig 2 Output divider Note the two milliampermeters and two resistor levers

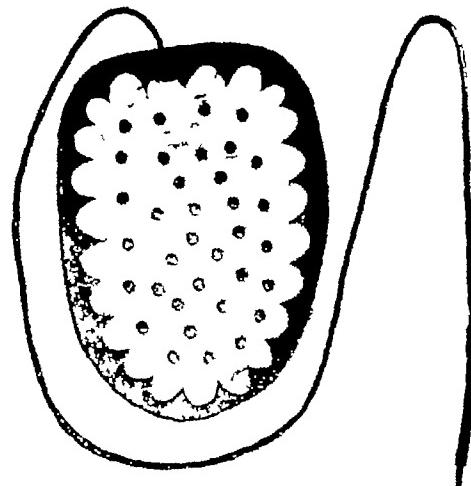

Fig 3 Front electrode accommodates not more than 4,000 milliamperes (16.5 X 11 inches)

tached string. This new type forceps makes the retrieving of the radium tube easy. The forceps grasps the tube readily, prevents its slipping or rotating out of the axis of the canal, and renders easy its withdrawal through the internal os.

SUMMARY

1 A new forceps is described which facilitates the introduction of tubes into the cervical and uterine canals.

2 This forceps can be used for inserting the Kaplan colpostat and cork in the vagina.

3 It may also be used as an extractor for tubes "lost" in the intra-uterine canal.

4 The name "uterine intubator" suggests the purpose of this new forceps.

tion of the super-power diathermy machine. Photographs of all apparatus, including its application to the treatment of one case at a time, have already been published,¹ but for the sake of simplicity and clearness it is thought advisable again to present photographs of the integral parts of the diathermy set-up, including the new output divider, showing two patients under treatment.

It was found that, when one has a number of patients to treat by means of elevation of general body temperature with the new diathermy machine, the cost of the individual treatments and the length of time required to administer a single treatment were prohibitive for many patients. It was due to the ingenuity and electrical knowledge of Mr H D Roop and Mr T T Magnuson, and their personal knowledge of the complicating factors, such as the giving of one treatment at a time, that the output divider was devised. This apparatus has permitted us to treat two patients simultaneously and, therefore, has resulted in a

THE SUPER-POWER DIATHERMY MACHINE WITH AN "OUTPUT DIVIDER"

By J F HAMILTON, M.D., Willis C Campbell Clinic, Memphis, Tenn

Our particular purpose is to call the attention of the profession to this new device, the output divider, in the practical applica-

insertion of a rubber sound containing two or more radium tubes is difficult with the ordinary forceps now generally used, as a slight resistance to the tube causes it to bend and rotate out of the forceps and to leave its position in the canal, often necessitating readjustment of the tube with the unprotected hand.

A new type forceps designated as a uterine intubator has, therefore been devised which avoids the difficulties mentioned. It has the shape of a double curved uterine dilator, with finger eyelets at one end and a pair of small blades at the other end. These blades are one inch long and cylindrical in shape, forming a $\frac{3}{8}$ -inch circular arc and making an angle of 30 degrees with the shaft of the forceps. The inner surfaces are grooved lengthwise. The blades are large enough to handle all types of radium tubes

and thin enough to render additional dilatation of the cervix unnecessary while the radium tube is being inserted. When the tube is grasped by the blades of the forceps, it is automatically adjusted in place by the ordinary finger pressure on the forceps handles. This factor becomes especially helpful when the physician is using large rubber sounds which must be gradually pushed into the canal by several to-and-fro movements.

In using the Kaplan colpostat for the treatment of malignancy of the cervix, the rubber corks are usually inserted by hand. This new type forceps readily grasps these rubber cylindrical applicators and makes their placement in the vagina safe and easy.

The small capsule radium applicator, ordinarily employed in the treatment of metrorrhagias, occasionally gets lost in the uterine canal, due to the breaking of the at-

Fig. 1 Left to right—patient, output divider, super-power diathermy machine, with nurse at control, and patient. This shows the double treatment set-up.

output of the diathermy equipment, each patient, however, being in series with the milliamperemeter and variable resister. The operator can thus not only accurately divide the total output between the two patients but has the means of observing the amount of current each patient receives.

We have found that around 8,000 ma is all that can be obtained from the machine when two patients are treated with only the standard number of electrodes being applied. It is said, however, that the full 10,000 ma could be utilized, if more electrodes were inserted in the circuit. This has not been necessary, as, with only 3,500 ma, we have been able to obtain 104° F. in one and a quarter hour.

The material we are using as electrodes is somewhat different from what was originally used, in that the electrode foil is about 0.2 mm thick, which, in turn, is about one-fifth as thick as that originally used. This thinner material conforms more closely to the contour of the body and is naturally much lighter than the thicker variety. The configurations made into the original electrodes are not incorporated in the thin plates for two reasons: first, we have not found it to be necessary; second, the thinness of the material will not permit so much to be cut away. Our electrodes are made here in the Clinic.

AN X-RAY BOARD FOR OBTAINING ROENTGENOGRAMS OF ANIMALS IN THE HORIZONTAL AND UPRIGHT POSITIONS

By ALTON OCHSNER, M.D., and
I M GAGE, M.D.

Department of Surgery, Tulane University School
of Medicine, New Orleans, Louisiana

The need for a suitable contrivance for obtaining roentgenograms of experimental animals in various positions is apparent. The ordinary clinical roentgenographic table

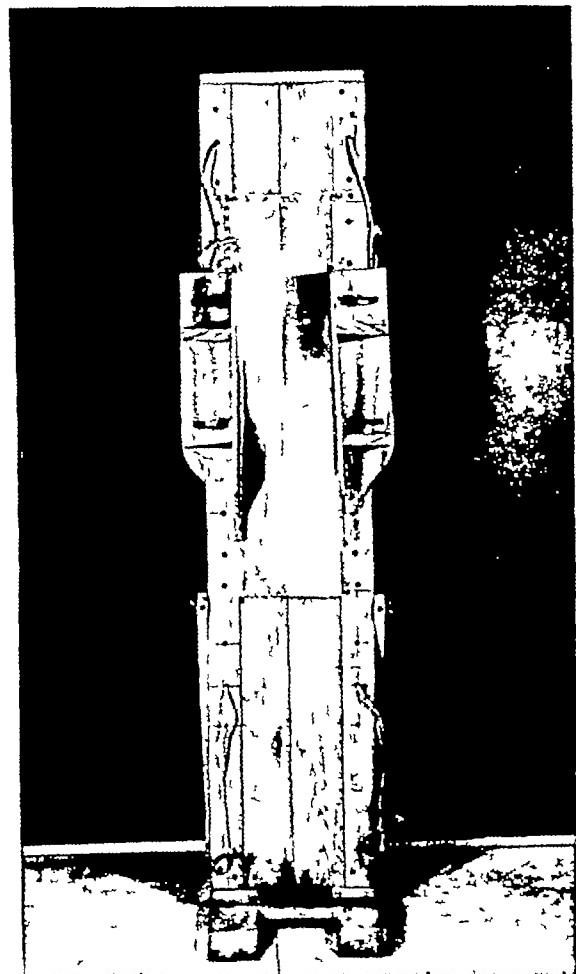

Fig 1. Anterior view of table in the upright position, showing the side boards which are adjustable from side to side and also from end to end.

is practically of no value for use in roentgenography in animals. By means of a board described by Stewart,¹ satisfactory roentgenograms can be obtained in the horizontal position. However, considerable difficulty is encountered in obtaining roentgenograms in positions other than the horizontal.

In the experimental laboratory, as well as in the clinic, the desirability of obtaining roentgenograms, especially in the upright position, is at once apparent, especially in experiments involving the thoracic viscera in which the possibility of the occurrence of

Fig. 4 Back electrode (16 X 10 75 inches)

great saving in time and expense to the patient. We have given about twenty-eight double treatments up to this time, using the new device, and so far it has proved satisfactory with one exception, when the two patients complained simultaneously of getting a shock at the moment the machine was turned on. Of course, the current was immediately cut off. The divider was examined, a short circuit strap installed, and since then not the slightest shock has been experienced.

The output divider consists of a pair of milliamperemeters and a pair of variable resistors, the whole constituting an accessory control which is inserted into the output circuit of the super-power machine.²

The electric circuit of the output divider is so arranged that when it is in use two patients are connected in parallel across the

position, because no pressure is exerted on the intestine by the vertebral column

In order to obtain roentgenograms of the various portions of the body with the animal in different positions, a modification of the Stewart board was constructed (Figs 1, 2, 3 and 4). The board is made in such a way that roentgenograms can be taken in the

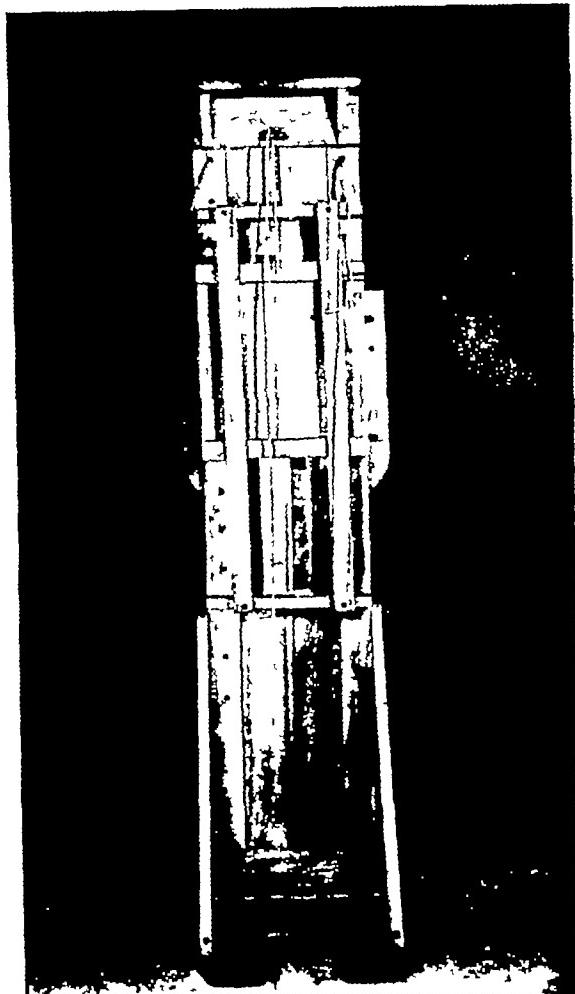

Fig 2 Posterior view of board in the upright position, showing the braces extending from the board down to the base. The plate carrier, which is adjustable, i.e. can be raised or lowered to suit the particular region and animal, is illustrated

horizontal, upright, or intermediary positions between the horizontal or the upright without changing the animal on the board

The board proper is composed of $\frac{3}{4}$ -inch lumber. On either side a piece $2\frac{1}{2}$ inches wide by 5 feet long extends the entire length of the board. At each end a 2×4 , $12\frac{1}{2}$ inches long is used to connect the two side pieces mentioned above. The center $8\frac{1}{2}$ inches of the 2×4 s is beveled in such a way that at the center the greatest depth measures six-eighths of an inch. This is so done that a trough-like depression is pro-

VISUALIZATION OF BILIARY AND PANCREATIC DUCTS BY THE USE OF SODIUM IODIDE

By RALPH L. TROUP, M.D., Department of Roentgenology, Green Bay Clinic, GREEN BAY, WISCONSIN

A male, aged 30, came to the Clinic for an examination on January 1, 1930, with a chief complaint of chills, fever, and jaundice of two years' duration. In 1919, the patient had had a cholecystostomy performed for chills, fever, and jaundice. Following this he felt well until March, 1928, when he developed severe chills followed by fever and became jaundiced for several days. He continued to have these attacks more

frequently until September, 1928, when cholecystectomy was performed. Following this, the patient obtained relief for three months when the same trouble reappeared. This time he had severe chills, lasting for

diastolic. His pulse rate was 70 and his temperature normal.

Laboratory Examination.—Blood count hemoglobin 65 per cent, erythrocytes 3,920,000, leukocytes 4,900. Fractional test meal total acidity 20, free hydrochloric acid, 16. Blood Wassermann, negative.

The roentgenologic examination of the stomach was negative.

The diagnosis of common duct stone was made and exploration was advised, but this was not done until March 2, 1931. When he opened the abdominal cavity, the surgeon found very dense adhesions with many small pockets containing vaseline, which had been poured into the wound at the last operation. He was finally able to dissect the liver free from adhesions and to discover the stump of the gall bladder. Because of the patient's poor condition, a mushroom catheter was sutured into the stump of the gall bladder. The patient made an uneventful convalescence and much bile drained through the catheter.

Two weeks following operation, sodium iodide was injected through the catheter until the patient complained of distress. One ounce of 12 per cent solution was used and a roentgenogram was made. The roentgenogram (Fig 1) showed I, Drainage tube, II, pancreatic duct, III, dilated common bile duct, IV, cystic duct, V, stump of gall bladder, VI, junction of common bile duct and pancreatic duct, VII, dye seen in duodenum, VIII, hepatic duct, IX, right and left hepatic ducts and some of the biliary tree in liver.

Figure 2 is an enlargement of Figure 1 to show I, Drainage tube, II, pancreatic duct, III, dilated common bile duct, IV, cystic duct, V, stump of gall bladder, VI, ampulla of Vater—showing negative shadow occupied by stone with narrow band of dye along stone passing into the duodenum, VII, dye in duodenum.

A second attempt to remove the stone was made on June 10, 1931. This was not ac-

Fig 1 See text

from thirty to sixty minutes, with an associated fever. He also became nauseated and vomited, and marked jaundice was present, with some pruritus. During the past two years he has had attacks once a month, lasting for several days, but for the five weeks previous to examination the attacks have occurred once or twice a week being much more severe than the previous ones. Following an attack, he becomes very weak and prostrated. His stools were usually acholic, and the urine very dark.

Physical Examination.—The patient was apparently very sick. The skin and sclera were jaundiced II, the liver palpable in the midline and tender II on pressure. The spleen was palpable on inspiration. He had hemorrhoids II. The feces were acholic. His blood pressure was 110 systolic and 80

complished because the surgeon opened the large bowel in attempting to free the adhesions. The abdomen was closed, the tube

right. The tube was removed in the early part of September and the wound healed promptly.

Fig. 2 See text.

being left in, and the patient made an uneventful convalescence. In July, 1931, a large amount of sour, greenish material came from the tube. This was examined and found to be gastric contents. The patient was given methylene blue, which drained from the tube in a few minutes. Due to the loss of a large amount of gastric contents, the patient felt very weak, so the tube was clamped off and he soon felt all

COMMENT

This case is reported because of complete visualization not only of the biliary tract but also of the pancreatic duct. A fistula was evidently established between the duodenum and the common duct, probably due to ulceration of the stone into the duodenum. The patient experienced no untoward effects from this injection of sodium iodide and to-day feels perfectly well.

METHODS OF MEASURING RADIANT ENERGY

The present writer for years has stressed the necessity of measuring the intensity of radiant energy as used in physiologic or therapeutic work. In a recent critique, Coulter and Smith¹ have the following to say. "In respect to these experiments and many similar ones, it would be impossible for another group of investigators to duplicate the dosage, as apparently neither the quantity nor the quality of the radiation was sufficiently measured nor is it recorded that variations of the individuals were considered. Thus the use of ultra-violet radiation in secondary anemia is still in the experimental stage." According to Davis,² of the Laboratories of the Desert Sanatorium and Institute of Research, Tucson, "It must be admitted that at present little knowledge is available to the diagnostician to enable him to determine proper dosages of radiant energy. The medical profession has knowledge of some important principles of heliotherapy which clinical experience and biologic experimentation have indicated. But in the case of John Jones, suffering with a particular type and severity of arthritis or with surgical tuberculosis in a certain stage, it is impossible at present to say just what

doses of sunshine or of artificial radiation will exert the most beneficial influence toward recovery. Yet it is evident that such an optimal dosage must exist. We do know that excessively large doses are injurious and that excessively small ones are without discoverable effect. In between such values must lie a value which is best for John Jones in his particular condition. The color and texture of his skin, the sensitivity of his reflex centers, his mental condition, and many other factors may influence his reactions to irradiation. Therefore, the problem of determining the optimal dosage for him is complicated and difficult of solution. Reliable measurements of the intensity and wave length of the radiation used in irradiation experiments are of first importance. Ideally, we should know the radiant power at each wave length employed, at every instant during the time of irradiation. Actually it is very difficult in many cases to measure those quantities continuously while the experiment is in progress."

The methods available for measuring and specifying the total amount of energy emitted by a source, as well as its spectral distribution, may be placed in two groups. There are those employing accurate physical methods, such as thermo-electric measurements (radiometry), chemical reactions (including spectrophotometry), the discharge of electrons, etc. In contrast to these accurate physical methods, the mastery of the technic of which is really, after all, not nearly so difficult as that of many of the clinical laboratory and operative procedures now commonly used, are numerous photo-biologic and photo-chemical procedures, designed for rapid and easy use. These latter methods merely gauge the gross intensity of ultra-violet, either total or of certain wave

doses of sunshine or of artificial radiation will exert the most beneficial influence toward recovery. Yet it is evident that such an optimal dosage must exist. We do know that excessively large doses are injurious and that excessively small ones are without discoverable effect. In between such values must lie a value which is best for John Jones in his particular condition. The color and texture of his skin, the sensitivity of his reflex centers, his mental condition, and many other factors may influence his reactions to irradiation. Therefore the problem of determining the optimal dosage for him is complicated and difficult of solution. Reliable measurements of the intensity and wave length of the radiation used in irradiation experiments are of first importance. Ideally, we should know the radiant power at each wave length employed, at every instant during the time of irradiation. Actually it is very difficult in many cases to measure those quantities continuously while the experiment is in progress."

The methods available for measuring and specifying the total amount of energy emitted by a source, as well as its spectral distribution, may be placed in two groups. There are those employing accurate physical methods, such as thermo-electric measurements (radiometry), chemical reactions (including spectrophotometry), the discharge of electrons, etc. In contrast to these accurate physical methods, the mastery of the technic of which is really, after all, not nearly so difficult as that of many of the clinical laboratory and operative procedures now commonly used, are numerous photo-biologic and photo-chemical procedures, designed for rapid and easy use. These latter methods merely gauge the gross intensity of ultra-violet, either total or of certain wave

President of the Radiological Society of North America

lengths, but give no information as to the relative intensity of the wave lengths in that region. Many of them are worthy of only passing mention, such as that of Bang³ and of Angus⁴ based on the rate of killing of bacteria and infusoria, respectively, and of Koeppe⁵ based on the extent of hemolysis produced in a suspension of red blood cells in quartz test tubes. Erythema following irradiation has been emphasized as a means of estimating the intensity of ultra-violet radiation, because many believe that the only biologically important wave lengths are those which produce erythema. Luckiesh⁶ advocates the use of the erythema curve, as a parallel method or basis of appraisal to measuring devices, because it encompasses a range of maximum biologic importance, and because the maximum of effectiveness is at a wave length (297 m μ) either coincident with or fairly close to that of the antirachitic maximum. The papers by Hausser,⁷ Hausser and Vahle,⁸ Luckiesh, Holladay, and Taylor,⁹ and Uhlmann¹⁰ give detailed information concerning the relative effects at different wave lengths.

Some time ago Hausser and Schlechter¹¹ pointed out that the effectiveness of radiation in the production of erythema does not merely depend upon wave length, because the quality of erythema is different according to the wave length of the radiation used to produce it. For instance, if the minimal amount of energy which gives rise to a mild erythema of Grade 1 be determined for certain wave lengths, and then multiples of this be used, a similar effect is

not obtained for the different wave lengths. While the degree of erythema produced by an irradiation with 254 m μ slowly increases as the duration is prolonged, the increase is very rapid for wave lengths around 313 m μ , so that doubling or trebling the dose leads to blister formation. The time course of the appearance and disappearance of the erythema is also quite different, that at 253 m μ appearing some time after the maximum effect has been reached at 297 m μ , and disappearing very much more quickly. In other words, taking the "erythema dose" as a biologic measure of radiation may lead to considerable error.

Of the photo-chemical methods, that of Clark¹² stands pre-eminent, and it has been much used in clinical and qualitative laboratory work. Clark proposed that the intensity (in ergs per sq cm per second) necessary to darken lithopone paint to a reflection factor of 50 per cent be taken as a unit of intensity of ultra-violet. There is no perceptible darkening when the paint is irradiated through ordinary window glass with cut off at 320 m μ . The light-sensitivity of lithopone is described by Brickwedde.¹³ In 1929, Clark¹⁴ substituted chemically pure zinc sulphide, moistened with lead acetate, for the lithopone. Recently (1931), she has given¹⁵ some results on the ultra-violet, to which the method is sensitive, in Baltimore sunlight.

The method of Anderson and Robinson¹⁶ is based on the decomposition of oxalic acid in solution with uranyl sulphate, the milligrams of oxalic acid decomposed, determined by titration against a standard permanganate solution, being calculated to ergs. Pohle¹⁷ developed the Berlin and

Meyer method in which a solution of hydriodic acid in water frees iodine under the influence of intense energy Webster, Hill, and Eidinow¹⁸ take the amount of bleaching, found to be proportionate to the length of exposure, of methylene blue in an acetone-methylene blue mixture in quartz tubes as indicative of the intensity of ultra-violet. In a later paper Hill¹⁹ reported that the standard color tubes made with methylene blue do not keep well, especially in warm weather, and recommended that they be made with copper nitrate and potassium chloride Kimball and Hand²⁰ believe that this method gives only approximate comparisons from day to day, dependent upon many factors, such as the purity of the chemicals and their temperature. Numerous fluorescent "actinometers" have been developed, for example those of Gennant,²¹ Pfund,²² and Anderson and Gordon²³

A number of investigators have made use of the cadmium photo-electric cell notably Dorno,²⁴ as well as Pohle and Sawyer,²⁵ Griffith,²⁶ and Harris²⁷ Burt, at Pasadena, has developed an ultra-violet photometer, the essential feature of which is a quartz bulb photo-electric cell, the inside of which is coated with sodium. The Westinghouse Electric and Manufacturing Company has

also developed a photo-electric cell method with a graphic recording device Kunz and Shelford²⁸ have recently reported on gas-filled photo-electric cells for measuring sunlight under various conditions Some of the cells exhibit a direct proportionality between intensity and current up to a certain limit Stockbarger and Burns²⁹ describe a method in which photo-electric cells and filters can be used to measure intensities of radiation within narrow regions by employing the flicker principle

Any device which has a peculiar sensitivity curve, such as most, if not all, photo-electric cells have, despite its high sensitivity in a particular part of the ultra-violet ($c\eta$, 300-320 m μ), has limited applicability It simply gives information concerning the relative amounts of energy emitted by a source at particular wave lengths The writer has never been able to become even mildly interested in any method which gives merely an approximation of the amount of ultra-violet of certain wave lengths being emitted by a certain source The explanation of such an interest is due to the overpowering effect of the demonstration that certain wave lengths in this region are anti-rachitic This has been injudiciously allowed to warp the judgment of many into believing that these same wave lengths, or nearby ones, are the only ones effective in many conditions

The radiometric method, using a thermopile or thermocouple connected with a high sensitivity galvanometer, with a definite response proportional to the incident energy intensity at all wave lengths, is always the court of last resort, since photographic and photo-electric instruments must be standardized by reference to some non-selective device Radiometry is the elite method for measuring radiant power It involves the measurement of the heat produced when ra-

diation is absorbed, the intensity being expressed quantitatively as the number of calories, or ergs, produced per unit area of absorbing material Radiometers are non-selective, having blackened receiving areas, that is to say, they are equally sensitive to all wave lengths of the radiant energy spectrum In consequence, all energy, regardless of wave length, is absorbed and transformed into heat The responses of non-selective receivers are directly proportional to the intensity of the incident radiation because, for the small rise in temperature involved, the thermal electromotive force is directly proportional to the heat generated, which in turn is directly proportional to the energy absorbed The advantage of the thermal junction over other methods is the ease and accuracy with which it can be calibrated to obtain the measurements in absolute value by resorting to the use of standardized incandescent lamps, operated at a defined voltage or current, and with the intensity of the total radiation at a fixed distance, and in a definite direction, known to a high degree of accuracy Coblenz³⁰ has given particularly good accounts of this method His papers and other pertinent literature are referred to in a publication by Laurens and Mayerson³¹

The use of screens or filters, even when corrections are made for reflection and absorption, to give the percentage values of the ultra-violet, luminous, and infra-red is only an approximate method, although very convenient and extensively used (Gibson³²) Filters to give certain regions of the spectrum may be used when, because of the impossibility of obtaining required intensity, it is not feasible to isolate the desired regions by means of a monochromator The advantages of filters lie in their simplicity

and conservation of energy They do not, however, afford the analysis possible with a spectrometer Jones³³ has recently developed a number of filters made up of selectively absorbing materials

To supplement results obtained with filters, radiation should be dispersed by monochromators or spectrometers, having optical parts transparent to ultra-violet and infrared as well as to luminous energy, and the energy in consecutive narrow bands measured by means of a linear thermopile, placed at the exit slit, connected with a galvanometer With such instruments one may determine the distribution of the radiant energy (per cent of the total) emitted by various sources in narrow bands of the three major spectral divisions (ultra-violet, luminous, and infra-red), the wave length limits of the transmission of filters, as well as the wave length percentage transmission of filter (*i.e.*, the percentage of the incident radiation which gets through after the loss suffered by the transmitted rays due to reflection and scattering)

For simply determining the wave length transmission of substances in the ultra-violet and visible regions of the spectrum, spectrograms are all that are really necessary These give the cut-off in the ultra-violet and qualitatively indicate any absorption at longer wave lengths Spectrograms, of course, also indicate the general nature of emission spectra McNicholas³⁴ and Davis and Sheard³⁵ describe the methods The spectro-photometric method consists essentially in determining at what wave length two contiguous spectra are of equal density, and this value, by this method, is independent of the kind, the law, the chromatic sensitivity, or the length of development of the plate as well as independent of the kind of

developer, the variations in the intensity of the source, and the length of the exposure. The per cent transmission is determined arbitrarily by the ratio of sector openings, the wave length being the dependent variable. For the details of the method the papers by Laurens and Mayerson,³¹ McNicholas,³² and Davis and Sheard³³ may be consulted.

The spectro-radiometric method gives results which are in agreement with photographic determinations made with a sector photometer and quartz spectrograph in the ultra-violet and visible. But, since the photographic method is not readily adapted for measuring the intensity of radiation in the infra-red, only part of which can be photographed by the use of very specially sensitized plates, the radiometric method is the only one to use in determining the intensity of dispersed infra-red. Anderson, Fraser, and Bird³⁴ did an important service in calling attention to the necessity of a consideration of the transmission of ultra-violet by quartz monochromators. They found that the transmission of a monochromator varied between 20 per cent for wave length 248 m μ , and 88 per cent for wave length 404.5 m μ . Forsythe and Barnes³⁵ state that the transmission of a monochromator of theirs is about 25 per cent at 260 m μ , about 40 per cent at 360 m μ , and about 48 per cent at 600 m μ .

There are a number of points which may be cited to show further the necessity of making measurements of this sort. (1) If the energy distribution of a source changes, due to variation in power input, then the transmission of a screen will also change, for example, it is necessary to determine the transmission in terms of the energy input of the source of energy. (2) In the making of screens manufacturers have difficulty in reproducing the same conditions in different melts, so that the cut-off in the ultra-violet,

as well as the transmission as to wave length, varies in different samples of the same kind of screen. In order to obtain exact data it is necessary to determine these factors on samples from each melt. (3) The drop in the transmission curve in the ultra-violet for screens is not a sharp one, but it covers a region of several wave lengths in sweeping from nearly full transmission to absolute cut-off, neither of which points represents the effective cut-off. The zero limit of transmission ascertained from a spectrogram may thus be a misleading measure of the value of a material for purposes of ultra-violet transparency. A screen transmitting to 270 m μ is likely to absorb a large portion of the energy in the neighborhood of 300 m μ . Spectro-radiometric and spectro-photometric determinations of transmission in terms of the energy distribution of the source give this information. (4) Of outstanding interest in connection with the transmission of screens, and in particular of some of the substitutes for quartz, is the fact that the percentage transmission, total and as to wave length, decreases with increasing duration of exposure to sunlight and artificial radiation. Nothing could illustrate more cogently, unless it be a deteriorating mercury lamp, the necessity of constantly making radiometric and photometric measurements to determine the total amount of energy, its spectral distribution, the shortest and longest wave lengths transmitted, and to what extent. (5) When using a screen that has a cut-off let us say between the ultra-violet and the luminous, we must not forget that it probably has a cut-off somewhere in the infra-red. Suppose we have an amber glass, for example, Corning Noviol O, with a cut-off at 370 m μ everything shorter than this being absorbed, with a typical percentage transmission from here up through the luminous. It is seldom realized that the transmission, though it continues into the infra-red region, eventually decreases, so that at about 3,500 m μ the glass transmits

³¹W. T. Anderson, H. D. Fraser and L. F. Bird. Jour. Optic. Soc. Am., 1928, XVII, 454.

³²W. E. Forsythe and B. T. Barnes. Rev. Sci. Instr.

1930 I 569

only 25 per cent of the incident energy (see Laurens and Mayerson³¹) To disregard this infra-red cut-off will give rise to error in the calculation of the distribution of energy between the ultra-violet, luminous, and infra-red portions, particularly if there is much energy in the infra-red spectrum of the source at longer wave lengths than this Solar radiation contains not very much, that of the carbon arc, more As a matter of fact, the infra-red absorption is not much greater for yellow glasses than for white

In order to know just how much energy is being administered it is essential for anyone working on the influence of sunlight to measure solar and sky radiation both spectrographically and radiometrically At our laboratory, spectrograms of the sun are made in order to show the shortest wave length present for the time of day, season, etc., and the total intensity of the radiation is then determined pyrheliometrically Marvin and Kimball³² describe various forms of the pyrheliometer For sunlight we use the one described by Gorczynski³³ This instrument built by Jules Richard of Paris, consists of a large Moll surface thermopile and a registering millivoltmeter It is a handy, sensitive, and accurate instrument It is carried on a clock-driven equatorial mounting which, with a hand-operated altitude and azimuth adjustment, maintains the surface of the thermopile at right angles with the incident rays The calibration of the instrument and of the recording millivoltmeter is described by Laurens and Mayerson³¹ By the use of appropriate screens, not only is the total amount of energy from the sun determined, but its distribution between ultra-violet, luminous, and infra-red as well We also use one of the thermo-electric pyrheliometers of Kimball and Hobbs,³⁴ as made by the Eppley Lab-

oratory This thermopile, attached to a recorder, permits of the determination of the total radiation from the sun and from the dome of the sky The instrument is calibrated so that the record of the thermo-electric current is read as g cal per sq cm per minute By means of screens it is again possible to obtain values for the distribution of the energy

RADIOLOGY AND PATHOLOGY

In the practice of any medical specialty, there is more or less dependence upon and interrelation with the other specialties The axiom, "No man liveth unto himself alone," may well be stated "No specialist practiseth unto himself alone" In spite of modern specialization, the human body still remains as a unit, and a patient with symptoms referable to one specialty may have the cause of these residing in an organ within the domain of still another Because of the breadth of each and its importance to all specialties, radiology and pathology stand in a unique as well as an important relationship to one another Radiology makes use of the roentgen ray and radium in the study, diagnosis, and treatment of disease Pathology marshals and uses every possible phase of pure and applied science in examining products and portions of the body that may be obtainable for the purpose of aiding in the diagnosis and treatment of disease

Modern diagnosis rests firmly upon the foundation of these sciences No one realizes it more (perhaps unconsciously) than the laity, for whom an X-ray examination or blood test has a well known fascination Every radiologist and pathologist is familiar with the individual who wants an X-ray examination or blood test, who, when questioned, states that he is merely sick and

³¹C F Marvin and H H Kimball Jour Franklin Inst 1926 CCH 273

³²L Gorczynski Jour Optic Soc Am 1924 IX 455

³³H H Kimball and H F Hobbs Jour Optic Soc Am 1923 VII 707

wants to find out what is the matter If either of these sciences were to be suddenly removed from modern medicine, the entire structure would collapse Some of the old-school clinicians decry the progress of modern medicine in these directions, but they do not seem to impede its progress Every clinical practitioner needs the fact finding these sciences offer There is the occasional clinician who insists that he needs neither, perhaps there is that rare individual whose diagnostic acumen has little need for them, but nevertheless there still remain many fine points of differential diagnosis that are radiologic or pathologic in character

Fundamental training in pathology has long been recognized as being both desirable and important for the clinician This is evident in undergraduate and post-graduate schools In the former, pathology is a major subject in sophomore and junior years, and in post-graduate schools from six months to a year is required to precede the clinical training In radiology, however, it is even more important than in the other specialties that there be a thorough training in pathology The proper interpretation of variations in density on an X-ray film is certainly achieved through a knowledge of those changes which produce them Familiarity with the gross and microscopic appearance of tissue, with the resultant process of disease in terms of tissue change, rather than as a clinical symptom, cannot but help to aid the radiologist greatly in his interpretations In addition, the proper interpretation of laboratory findings is always improved by familiarity with procedures and personal knowledge of limitations of technic Then there is the understanding and interpretation of tissue diagnoses and descriptions, so important for subsequent radiotherapy It cannot be expected that the radiologist be a tissue pathologist, but a certain knowledge of tissue pathology improves his ability to direct properly the treatment of cancer and to prognosticate the

effects of such treatment But even with the training suggested, the radiologist remains to a great extent dependent upon the pathologist

Discussion by the radiologist and pathologist of the nature and interpretation of laboratory findings in a given case is often of value in radiologic interpretation, diagnosis, and treatment This is most important in the treatment of neoplasms Proper radiologic therapy of cancer is often dependent on the interpretation of the microscopic findings, and the radiologist's prognosis is partly dependent on the interpretation of the pathology It need hardly be mentioned that knowledge of laboratory findings will often aid the radiologist in his interpretation of the X-ray film There are some radiologists, however, who work objectively, entirely, interpreting the findings as they see them, not desiring any information about the patient This attitude is scientifically commendable, but, practically, there is little question but that an interpretation given with knowledge of the clinical status of the patient is more valuable If a patient has a tubercle bacilluria, how much better that the radiologist should know it when interpreting a pyelogram

Co-ordination of clinical, radiologic, and pathologic findings is often difficult, and consultation and conference between the clinician, radiologist, and pathologist should be encouraged, although in the average hospital it is seldom done It is only by such means that proper co-ordination of results can be obtained Such conferences would lessen the incidence of bilateral pyelography on a patient with a low kidney function, and many other common apparent errors in judgment, but actually lack of proper co-ordination Most important of all is the conference between surgeon, pathologist, and radiologist in relation to cancer diagnosis and treatment The final diagnosis of cancer practically always rests with the microscope, but the problem of biopsy, and

limitation of surgical and radiologic treatment, can best be determined by these three individuals working as a team. The exact location for biopsy, the advisability of treatment immediately following biopsy, and the later treatment are not problems for a single individual but for a team. Any cancer is of sufficient importance to need the combined opinions of an experienced radiologist, pathologist, and surgeon for proper management.

As an example of increased efficiency in routine diagnosis, Bain¹ analyzed 347 cases for diagnosis, all of which had the co-ordinated work of clinician, radiologist, and pathologist. Of these, 51 per cent were diagnosed by clinical means, 35 per cent by radiologic, and 14 per cent by laboratory. These did not include post-operative tissue diagnoses.

From the radiologist, the pathologist has much to learn. This is most evident in bone pathology, in which the correlation of the roentgen film and microscopic study make the complete picture.

Many small communities and hospitals are unable to afford, or do not have material for, full-time specialism, hence there evolve men who combine two or more. Examples of these in relation to those specialists under discussion are surgeon-radiologist, internist-radiologist, surgeon-pathologist, internist-pathologist, and radiologist-pathologist. This latter combination, when possible, is the most desirable to consummate because of the close relationship between the two specialties and because they are both laboratory sciences. Individuals who combine them are quite indispensable.

Combined training in these two specialties, because of their fundamental nature, makes an excellent foundation for special training in other medical specialties and especially for general practice. With such

training there would be more intelligent use of these fundamental sciences.

With such close scientific and practical relationship existing between these sciences, it behooves those practising them as specialties to co-operate most fully, so that they may be better able to interpret their findings.

THE ANNUAL MEETING

The officers elected at the Seventeenth Annual Meeting, held in St Louis, from Nov 30 to Dec 4, 1931, are as follows:

President-elect, Byron H Jackson, M D, of Moses Taylor Hospital, Scranton, Pennsylvania; *Secretary-Treasurer*, Donald S Childs, M D, of College of Medicine, Syracuse University, Syracuse, New York; *First Vice-president*, W Herbert McGuffin, M D, of Calgary, Alberta, Canada; *Second Vice-president*, Col Henry C Pillsbury, M D, Chief of U S Army X-ray Service, stationed at the Presidio, San Francisco; *Third Vice-president*, John D Camp, M D, Mayo Clinic, Rochester, Minnesota. The *Librarian*, Charles G Sutherland, M B (Tor), Mayo Clinic, Rochester, Minnesota, succeeds himself.

The new *Chairman of the Executive Committee* will be Leon J Menville, M D, of Tulane University, New Orleans. The President and President-elect are, by the terms of the Constitution, members of the Executive Committee. The *two new members* are Frederick H Rodenbaugh, M D, of San Francisco, and Thomas A Burcham, M D, of Des Moines, Iowa.

The Committee on Scientific Awards reported that it had made a survey of the scientific exhibits and had endeavored to judge them both as to their scientific value and the excellence of their presentation. In making

limitation of surgical and radiologic treatment, can best be determined by these three individuals working as a team. The exact location for biopsy, the advisability of treatment immediately following biopsy, and the later treatment are not problems for a single individual but for a team. Any cancer is of sufficient importance to need the combined opinions of an experienced radiologist, pathologist, and surgeon for proper management.

As an example of increased efficiency in routine diagnosis, Bain¹ analyzed 347 cases for diagnosis, all of which had the co-ordinated work of clinician, radiologist, and pathologist. Of these, 51 per cent were diagnosed by clinical means, 35 per cent by radiologic, and 14 per cent by laboratory. These did not include post-operative tissue diagnoses.

THE ANNUAL MEETING

The officers elected at the Seventeenth Annual Meeting, held in St Louis, from Nov 30 to Dec 4, 1931, are as follows:

President-elect, Byron H Jackson, M D, of Moses Taylor Hospital, Scranton, Pennsylvania; *Secretary-Treasurer*, Donald S Childs, M D, of College of Medicine, Syracuse University, Syracuse, New York; *First Vice-president*, W Herbert McGuffin, M D, of Calgary, Alberta, Canada; *Second Vice-president*, Col Henry C Pillsbury, M D, Chief of U S Army X-ray Service, stationed at the Presidio, San Francisco; *Third Vice-president*, John D Camp, M D, Mayo Clinic, Rochester, Minnesota. The *Librarian*, Charles G Sutherland, M B (Tor), Mayo Clinic, Rochester, Minnesota, succeeds himself.

The new *Chairman of the Executive Committee* will be Leon J Menville, M D, of Tulane University, New Orleans. The President and President-elect are, by the terms of the Constitution, members of the Executive Committee. The *two new members* are Frederick H Rodenbaugh, M D, of San Francisco, and Thomas A Burcham, M D, of Des Moines, Iowa.

The Committee on Scientific Awards reported that it had made a survey of the scientific exhibits and had endeavored to judge them both as to their scientific value and the excellence of their presentation. In making

¹Walter G Bain. Illinois Med Jour., December 1927, 111 479.

the following recommendations (which were adopted), the Committee wrote "We wish to call attention to the immense amount of clinical material in this exhibit. In many cases your Committee found difficulty in making selections, owing to the exceedingly high value of all of the exhibits."

INDIVIDUAL EXHIBITS

First Place—Ira H Lockwood, M D, of Kansas City, Missouri "The Roentgen Examination of the Mammary Glands"

Second Place—Frank B Stephenson, M D, and Kenneth D A Allen, M D, of Denver, Colorado "Bone Tumors"

Honorable Mention—Paul F Cole, M D, of Springfield, Missouri "New Application of the Potter-Bucky Grid to Any Angle, with Special Reference to Head Work"

HOSPITAL GROUPS

First Place—Henry W Meyerding, M D, of the Mayo Clinic, Rochester, Minnesota "Diagnosis and Roentgenologic Findings in Spondylolisthesis"

Second Place—Samuel Brown, M D, of the University of Cincinnati Medical College, Cincinnati, Ohio "Thoracic Aorta"

Honorable Mention—John D Camp, M D, of the Mayo Clinic, Rochester, Minnesota (1) "Roentgenologic Changes in Intracranial Disease" and (2) "Roentgenologic Bone Changes in Hyperparathyroidism" John R Carty, M D, C V Kilbane, M D, Sidney Weintraub, M D, and John Remer, M D, of Cornell Clinic, New York Hospital "Some Unusual Thoracic and Gastric Lesions" Charles H Heacock, M D, Polyclinic Hospital, Memphis, Tennessee "Intravenous and Serial Pvelo-uterography"

REPORT OF PUBLICATION COMMITTEE

The Chairman, W Herbert McGuffin, M D, reported on the questionnaire recently

sent to the subscribers of *RADIOLOGY*, from 50 per cent of whom replies were received. Of these, 98 per cent responded that they were favorably impressed. At the Editorial Staff meeting, a summary of the replies received was read, and suggestions of value were offered and discussed by a considerable number of those present.

EXCELLENCE OF PROGRAM

There were 165 papers entered on the program, to which five days were devoted. The high degree of excellence of the entire program was a matter of comment by members and eminent visitors as well, the retiring President, Bundy Allen, M D, of Tampa, Florida, and his Program Committee, receiving well-earned praise.

COMMENTS ON MEETING

During one evening session a motion picture depicting the salient features of bone tumors was presented by Charles F Geschickter, M D, of the Garvan Cancer Research Laboratory of the Surgical Pathological Laboratory of the Johns Hopkins University and Hospital, Baltimore.

The same audience that listened to Dr Geschickter also was deeply interested in an address and motion picture presented by Francis Carter Wood, M D, of the Crocker Laboratory of Columbia University, New York City. The film shows with a wealth of detail the work of this great experimental and pathologic laboratory, and no "movie" ever held its audience more enthralled. At the close, Dr Wood explained upon what terms films are available for use before medical societies.

The registration at the meeting was 580, which may be considered a most excellent attendance. An eminent guest was present from Buenos Aires, Argentina in the person of Carlos Heuser, M D, who addressed the Society on the subject of arteriography by intravenous injection.

The several hundred who attended the

the following recommendations (which were adopted), the Committee wrote "We wish to call attention to the immense amount of clinical material in this exhibit. In many cases your Committee found difficulty in making selections, owing to the exceedingly high value of all of the exhibits."

INDIVIDUAL EXHIBITS

First Place—Ira H Lockwood, M D, of Kansas City, Missouri "The Roentgen Examination of the Mammary Glands"

Second Place—Frank B Stephenson, M D, and Kenneth D A Allen, M D, of Denver, Colorado "Bone Tumors"

Honorable Mention—Paul F Cole, M D, of Springfield, Missouri "New Application of the Potter-Bucky Grid to Any Angle, with Special Reference to Head Work"

HOSPITAL GROUPS

First Place—Henry W Meyerding, M D, of the Mayo Clinic, Rochester, Minnesota "Diagnosis and Roentgenologic Findings in Spondylolisthesis"

Second Place—Samuel Brown, M D, of the University of Cincinnati Medical College, Cincinnati, Ohio "Thoracic Aorta"

Honorable Mention—John D Camp, M D, of the Mayo Clinic, Rochester, Minnesota (1) "Roentgenologic Changes in Intracranial Disease" and (2) "Roentgenologic Bone Changes in Hyperparathyroidism" John R Carty, M D, C V Kilbane, M D, Sidney Weintraub, M D, and John Remer, M D, of Cornell Clinic, New York Hospital "Some Unusual Thoracic and Gastric Lesions" Charles H Heacock, M D, Polyclinic Hospital, Memphis, Tennessee "Intravenous and Serial Pseudo-uterography"

REPORT OF PUBLICATION COMMITTEE

The Chairman, W Herbert McGuffin, M D, reported on the questionnaire recently

sent to the subscribers of *RADIOLOGY*, from 50 per cent of whom replies were received. Of these, 98 per cent responded that they were favorably impressed. At the Editorial Staff meeting, a summary of the replies received was read, and suggestions of value were offered and discussed by a considerable number of those present.

EXCELLENCE OF PROGRAM

There were 165 papers entered on the program, to which five days were devoted. The high degree of excellence of the entire program was a matter of comment by members and eminent visitors as well, the retiring President, Bundy Allen, M D, of Tampa, Florida, and his Program Committee, receiving well-earned praise.

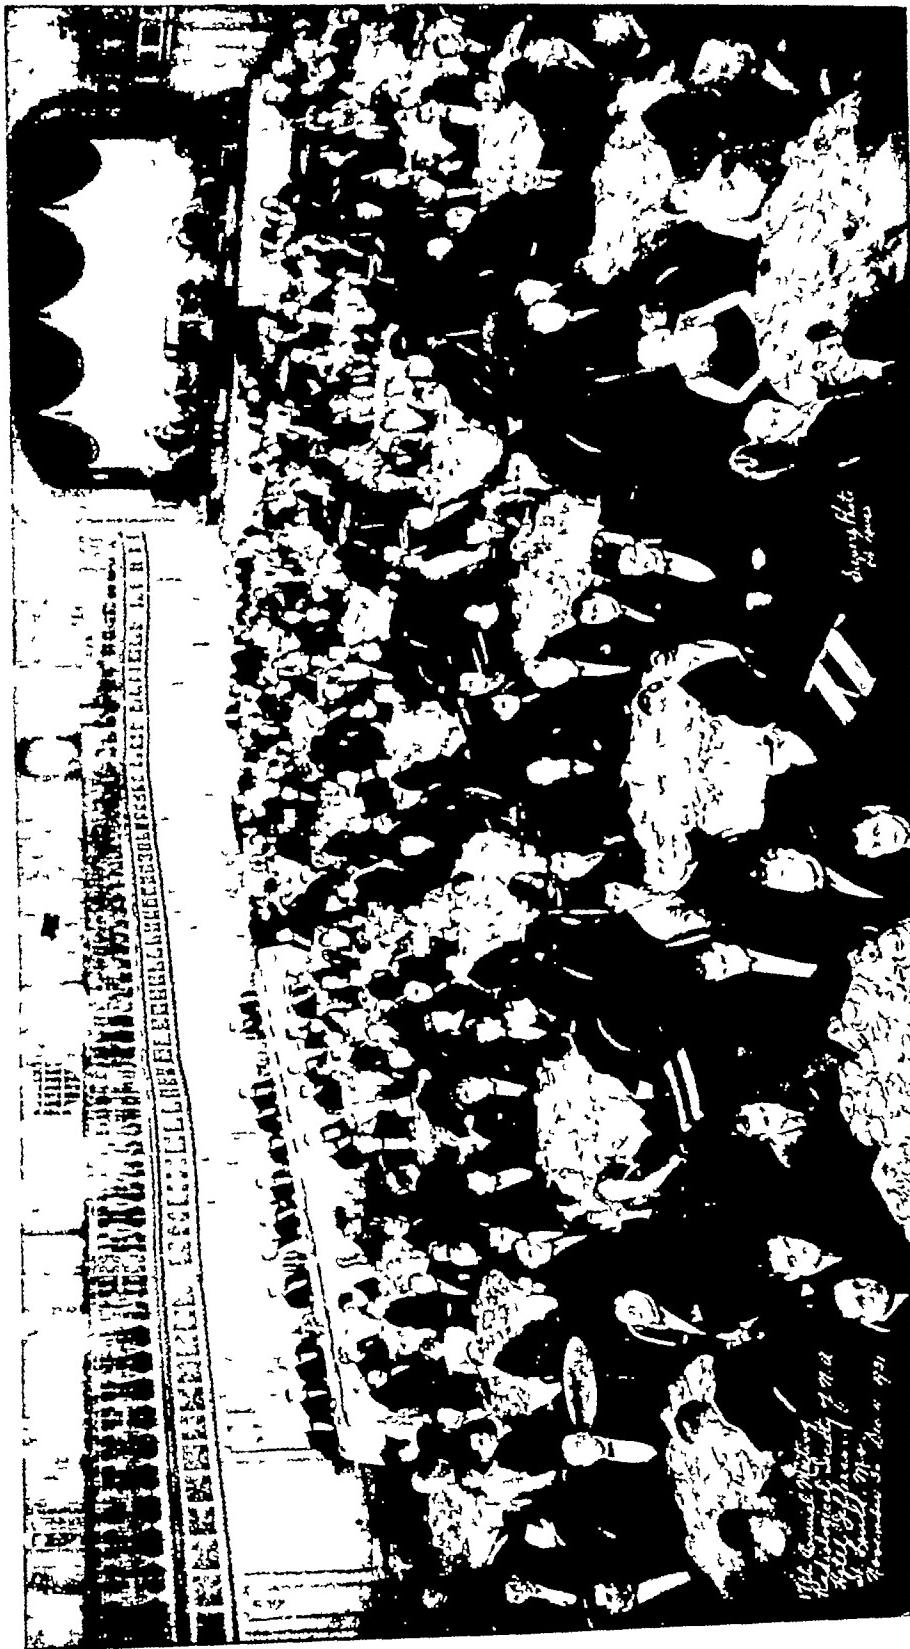

COMMENTS ON MEETING

During one evening session a motion picture depicting the salient features of bone tumors was presented by Charles F Geschickter, M D, of the Garvan Cancer Research Laboratory of the Surgical Pathological Laboratory of the Johns Hopkins University and Hospital, Baltimore.

The same audience that listened to Dr Geschickter also was deeply interested in an address and motion picture presented by Francis Carter Wood, M D, of the Crocker Laboratory of Columbia University, New York City. The film shows with a wealth of detail the work of this great experimental and pathologic laboratory, and no "movie" ever held its audience more enthralled. At the close, Dr Wood explained upon what terms films are available for use before medical societies.

The registration at the meeting was 580, which may be considered a most excellent attendance. An eminent guest was present from Buenos Aires, Argentina, in the person of Carlos Heuser, M D who addressed the Society on the subject of arteriography by intravenous injection.

The high degree of excellence of the entire program was a matter of comment by members and eminent visitors as well, the retiring President, Bundy Allen, M D, of Tampa, Florida, and his Program Committee, receiving well-earned praise.

COMMENTS ON MEETING

During one evening session a motion picture depicting the salient features of bone tumors was presented by Charles F Geschickter, M D, of the Garvan Cancer Research Laboratory of the Surgical Pathological Laboratory of the Johns Hopkins University and Hospital, Baltimore.

The same audience that listened to Dr Geschickter also was deeply interested in an address and motion picture presented by Francis Carter Wood, M D, of the Crocker Laboratory of Columbia University, New York City. The film shows with a wealth of detail the work of this great experimental and pathologic laboratory, and no "movie" ever held its audience more enthralled. At the close, Dr Wood explained upon what terms films are available for use before medical societies.

The registration at the meeting was 580, which may be considered a most excellent attendance. An eminent guest was present from Buenos Aires, Argentina, in the person of Carlos Heuser, M D, who addressed the Society on the subject of arteriography by intravenous injection.

The several hundred who attended the

banquet were wholly delighted with the musical program provided by the St Louis group, the musicians contributing to it being *artistes* of a high order. The address of the evening was delivered by the Honorable Joseph E. Ransdell, former United States Senator from Louisiana and present Executive Director of the National Institute of Health. He spoke with great earnestness of the Government's latest measures to promote public health, toward which the Chemical Foundation has contributed generously.

The floor plan of the hotel lent itself admirably to the accessibility of the commercial exhibit; in fact, the commercial exhibitors found themselves surrounded by the visitors at all times. The apparatus and drug houses which have exhibited with the Radiological Society in the past were all represented.

AWARD OF GOLD MEDALS

At the 1931 session of the Radiological Society of North America two awards of the Society's gold medal were made, one to M. J. Hubeny, M.D., of Chicago, and one to Carlos Heuser, M.D., of Buenos Aires, Argentina.

Dr. Hubeny has been a member of the Society since 1918, has served as President, as Editor of *RADIOLOGY* over a period of years represented by the first sixteen volumes of the publication, as President of the American College of Radiology, as Chairman and as Secretary of the Section on Radiology of the American Medical Association, and he has to his credit, besides, years of splendid work for the Society on committees. Yet it is not so much for his constructive work in the Society's behalf that the gold medal was awarded as for his achievements in the advancement of the science of radiology. He is credited with early work on focal infection which resulted

in the publication, in 1921, of an important paper on "Determination of Dental Focal Infection by Means of the Radiograph." Among his other published papers may be enumerated the following, the very titles of which will indicate the broad field of his study and investigation: "Injection of the Sphenoid Sinuses with a Suspension of Barium Sulphate" (1921), "Economics and Socialization of Medicine" (1926), and "The Oblique Projection in Examination of the Lumbar Spine." He is the author, with W. A. N. Dorland, M.D., of the standard text entitled, "Roentgenography in Embryology and Obstetrics," which has also appeared in a German translation.

Dr. Heuser has done outstanding work in the development of the clinical application of the X-rays since the year following their discovery by Wilhelm Rontgen, nor has he ceased to investigate in new fields, as attested by experimental work reported in recent years. Dr. Heuser made the long trip from his home in South America to attend this meeting of the Society.

FLORIDA RADIOLOGICAL SOCIETY ORGANIZED

The Florida Radiological Society, composed of radiologists practising in the State of Florida, was formally organized on Nov. 14, 1931, at St. Petersburg, Florida, under the temporary Chairmanship of L. W. Cunningham, M.D., of Jacksonville, Florida. A Constitution and By-laws were adopted at this organization meeting, and the following officers were elected to hold office until the spring meeting in 1932:

President—L. W. Cunningham, M.D., St. James Bldg., Jacksonville, Florida.

Vice-president—Orion O. Feaster, M.D., Power and Light Bldg., St. Petersburg, Florida.

Secretary-treasurer—Frederick K. Her-

pel, M D , Good Samaritan Hospital, West Palm Beach, Florida

Meetings of the Society will be held twice yearly, in November and in May, at the same time as the meeting of the Florida State Medical Association

ROENTGENOLOGICAL CONFERENCE

The New York Roentgen Society invites you to join with the New England Roentgen Society, the Philadelphia Roentgen Ray Society, and the roentgenologists of Baltimore and Washington in a Roentgenological Conference to be held in New York City on Friday, January 29, and Saturday, January 30, 1932 Headquarters- Hotel Pennsylvania

J BENNETT EDWARDS, M D , *Secretary*,
the New York Roentgen Society Address 144 Woodridge Place, Leonia,
N J

DECISION AGAINST THE LANGMUIR TUBE

A decision by the Supreme Court holds invalid the Langmuir patent on high vacuum tubes In refusing to grant a hearing to the General Electric Company, the Court, Justice Stone speaking, declared that the tube patent was invalid for want of invention In detail, it was said that the component parts were well known and had been employed to produce results similar to those produced by the Langmuir tube before the issuance of a patent upon the latter

OWNERSHIP OF ROENTGENOGRAMS¹

The question whether the roentgenograms of a hospital patient belong to the pa-

tient or to the hospital was answered by a court for the first time, so far as is known, in *Hurley Hospital vs Gage*, decided on appeal, April 21, by the Circuit Court for the County of Genesee, Michigan The patient had been roentgenographed in the roentgenographic department of the Hurley Hospital at Flint The usual charge for the service was included in the patient's bill He made a payment on account but refused to pay the charge for roentgenographic service unless the roentgenograms were delivered to him The hospital refused to deliver them and sued the patient for the balance due In the Justice's Court where the suit was instituted, judgment was given against the hospital The hospital, however, because of the principle involved, appealed to the Circuit Court of Genesee County At the hearing on the appeal, no one appeared on behalf of the patient and the case was heard and judgment rendered without the submission of evidence or argument by him

In giving judgment, the court pointed out that the hospital sold and patients paid for, not the material that went into roentgenograms, but knowledge and experience The protection of the hospital might depend largely on the proper preservation of the roentgenograms and, said the court, the films should remain with the hospital Judgment was given against the patient for the balance due on his bill, covering the amount charged by the hospital for the roentgenograms

CORRECTION

On page 898 of the October, 1931, issue of *RADIOLOGY*, in the abstract of the paper on "Roentgen Cataract Its Significance and Prevention," by Max Cremer, the last sentence should read as follows "A thickness of 13 mm of gold corresponds to a lead protection of 2 millimeters."

¹Reprinted by permission from *Journal of the American Medical Association* Vol. 101, No. 21, Nov. 21, 1931, NCVII, 1542.

banquet were wholly delighted with the musical program provided by the St Louis group, the musicians contributing to it being *artistes* of a high order. in roentgenographic interpretation, and contains a system of exceptionally good reproductions. By means of the detailed analyses accompanying the illustrations, the authors express the hope of aiding the physician in rendering an independent evaluation of his own films. This is undeniably the most logical didactic method, and the expert reader will find few occasions to disagree with the interpretations offered by the authors.

In the introductory paragraphs the value of technically good roentgenographic work is stressed, and the authors point to the superior differential diagnostic value of roentgenographic over purely roentgenoscopic data.

Included is a brief but thorough consideration of the normal chest in which the authors point out certain non-significant findings which are often the basis for misinterpretation by the inexpert. Nearly half of the volume is devoted to the roentgenologic manifestations of the various types and complications of pulmonary tuberculosis. It is the opinion of the authors that this subject is of particular importance to the general practitioner, because it is he who has most frequent opportunity to see this disease in its incipiency. The analysis is thorough, and in every sense practical.

Non-tuberculous lesions are treated under two headings (1) inflammatory, (2) neoplastic. Reproductions exemplifying the different types of pneumonia, pulmonary infarction, lung abscess, bronchiectasis, chronic bronchitis, passive congestion secondary to decompensated mitral disease, and silicosis are exhibited and analyzed in the text. Five examples of primary pulmonary carcinoma, accompanied by a discussion of the roentgenographic data, are given. The picture of pulmonary metastatic carcinoma, of Hodgkin's disease, lymphosarcoma, echinococcus cyst, and aortic aneurysm complete this section. The final section deals with the varieties of inflammatory disease of the pleurae.

The reader who has become familiar with thoracic pathology as manifested roentgenographically will, perhaps, find little that is new or very illuminating in this volume. For such, however, it was not prepared. The authors intended merely to supply the general practitioner with a guide to aid him in his interpretation and to indicate to him the manner in which thoracic disease is manifested on the properly executed X-ray film. It may be, however, that the expert will find perusal of this volume profitable, if only as an example of logical inference and clear exposition—a facility with which is not possessed by all.

AMERICAN MEDICAL ASSOCIATION OF VIENNA

"Hofrat Prof Holzknecht is dead", so ran the sad news rapidly over Vienna. And the whole world was cognizant of that sad story in less than twenty-four hours. The man who paved the way for scientific medical roentgenology has gone. Up until a few hours before his death he faithfully performed his duties and worked upon problems in his chosen specialty.

The members of the American Medical Association of Vienna are to-day grieving the loss of this great roentgenologist, who was truly a martyr. Our official representative to the funeral and memorial services in the Roentgen Institute of the Allgemeines Krankenhaus was Dr G von Poswick, whose interest in and appreciation of the work of Hofrat Prof Holzknecht are well known.

SERIES OF PAPERS BY THE COLE COLLABORATORS

An important series of papers is to be published in RADIOLOGY, which our readers may await with considerable interest. It is

"An Analytical Study of the Roentgenological Exploration of the Mucosa of the Gastro-intestinal Tract" by The Cole Collaborators, Lewis Gregory Cole, M.D., Robert Earl Pound, M.D., Russell Wright Morse, M.D., Courtenay I. Headland, M.D., William Gregory Cole, M.D., and Ames W. Naslund, M.D.

This material was presented in the form of a resume of data at the Third International Congress of Radiology in Paris last Summer. The complete series of papers will include the reports of personal communications from many leading American roentgenologists, an extensive study of the foreign literature, the assembling of material from various institutions, and the designing and actual construction of apparatus for applying the localized pressure technic. The

papers are to be illustrated by the finest type of reproductions of roentgenograms, with full explanatory captions.

The expense of reproducing illustrations of such supremely high quality, printed upon special paper, is, of necessity, great, and in excess of that which the Radiological Society of North America is able to finance. The Chemical Foundation has most generously offered to bear this additional expense, that readers of RADIOLOGY may have the splendid series presented in the most finished manner.

The honor of presenting this subject would, undoubtedly, have fallen to the late Preston M. Hickey, M.D., had he lived, and, considering this fact and the great honor and respect in which Doctor Hickey was held, not only by American roentgenologists but by specialists in this field throughout the world, the articles, when completed, are to be assembled in a bound volume as a memorial to the dean of American roentgenology Preston M. Hickey, M.D.

BOOK REVIEW

ROENTGEN ATLAS OF DISEASES OF THE LUNGS A MANUAL FOR PHYSICIANS (RONTGENATLAS DER LUNGENERKRANKUNGEN) By DR W BREDNOW Privatdozent fur innere Medizin und Rontgenologie an der Universitat Gottingen, and DR E HOFMANN, Gottingen. A paper-bound volume of 167 pages and 85 illustrations and 1 "Diaspositivfilm." Published by Urban and Schwarzenberg, Berlin, 1931. Price, 14 marks.

In a small volume the authors have dealt successfully with the problem of placing in the hands of the practitioner an atlas of roentgenograms exemplifying the more common varieties of pulmonary lesions.

The work was undertaken largely for the benefit of the physician not especially trained

in roentgenographic interpretation, and contains a system of exceptionally good reproductions. By means of the detailed analyses accompanying the illustrations, the authors express the hope of aiding the physician in rendering an independent evaluation of his own films. This is undeniably the most logical didactic method, and the expert reader will find few occasions to disagree with the interpretations offered by the authors.

In the introductory paragraphs the value of technically good roentgenographic work is stressed, and the authors point to the superior differential diagnostic value of roentgenographic over purely roentgenoscopic data.

Included is a brief but thorough consideration of the normal chest in which the authors point out certain non-significant findings which are often the basis for misinterpretation by the inexpert. Nearly half of the volume is devoted to the roentgenologic manifestations of the various types and complications of pulmonary tuberculosis. THE APPENDIX (DIAGNOSIS)

Clinical and Radiologic Diagnosis of Chronic Appendicitis Mario Buisson Minerva Med., May 12, 1931, XXII, 714-724

According to the author, the usefulness of radiography in the diagnosis of chronic appendicitis is not yet fully recognized. He answers the criticism of Bobbio and Buchmann by explicitly stating that of all the means available to the physician to-day, radiologic investigation is undoubtedly the best in its differentiating qualities, careful correlation of clinical and radiologic findings is obviously the diagnostic procedure of choice.

He notes that clinical diagnosis of chronic appendicitis relies almost exclusively upon pain detection in definite regions of the abdomen, pain which may or may not be caused by either direct or indirect action of a pathologic appendix. The importance often laid upon these tests is rather unfounded because the appendix is a mobile organ, the position of which is mainly determined by that of the cecum and of the colon, furthermore, its length is known to vary from 1 to 23 centimeters. The patient's history may not be of any substantial aid, because symptoms of chronic appendicitis are anything but clean-cut warnings.

The radiologic technic employed by the author consists in three consecutive daily administrations of from 200 to 250 gr of barium sulphate diluted in from 400 to 500 cc of water sweetened by syrup, in fluoroscopic examination of the patient at the most suitable times, and in the taking of radiographs in various positions.

Normal appendices are distinctly visible, the pathologic appendix is visible in 80 per cent of the cases, but its outlines are not sharply defined and its shadow is not homogeneous. The absence of the appendicular image is a certain indication of appendicitis, this having been always confirmed by surgical control. If the appendix is located, its state may be further ascertained by direct palpation. Fluoroscopic investigation affords a means of detection

of irregularities in the position of the appendix, its state of mobility, and the presence of adhesions. Irritation of the appendicular mucosa is characterized by the short time-interval in which the opaque food is retained in it. Furthermore, the author states that a pathologic appendix also alters the functions of the digestive tract, causing spasms of different natures and locations. He concludes by giving complete reports on eleven cases treated in his own clinic and illustrated by a large number of radiographs.

L MARINELLI

BLOOD CHANGES

The Effect of X-ray Therapy on the Partition of Phosphorus Compounds in the Blood in Disease M Sokolovitch Brit Jour Exptl Pathol., 1931, XII, 147-150

The administration of X-rays influences and causes changes in the partition of the P compounds of the blood. The free P of the blood plasma and that of the red blood corpuscles undergo a change, but it is not uniform. The ester P of the plasma shows a tendency to rise, and the ester P of the corpuscles to fall slightly in amount. The lipin P of the blood plasma shows a tendency to increase markedly and the lipin P of the red blood corpuscles to decrease markedly in percentage.

CHEMICAL ABSTRACTS

The Effect of Roentgen Rays on the Catalase Content of the Blood Geremia Antonio Minerva Med., May 5, 1931, XXII, 685, 686

The author has studied the effect of X-rays on the catalase content of the blood of rabbits and men. As a unit of catalase quantity, the fixation index of the red cells, as obtained by Rigoni's method, was assumed. His results show that in rabbits one SED caused a marked increase in hematic catalase inde-

pendently of the region irradiated Man showed changes of the same nature under hepatic or splenic irradiation, corresponding to one S E D at the surface, a dose of one-half S E D causing no appreciable change

The effects were detected two hours after treatment and remained unchanged or slightly weaker for two days, at which time they started to decrease rapidly and disappeared after ninety-six hours

The author ventures the hypothesis that the increase of catalase content in the blood is a manifestation of the destructive action of the radiation on the cells of the body

L MARINELLI

BONE (DIAGNOSIS)

Certain Radiographic Peculiarities in the Skeleton of an Acromegalic Giant E Forlini. L'Ateneo Parmense, January-February, 1931, III, 5-16

This article treats of the radiographic examination of the cranium and other parts of the skeleton of a female acromegalic giant who died of pulmonary and intestinal tuberculous ulcers, in 1889, at the age of thirty-one

The author's investigations, contrary to previous belief regarding acromegalia and acromegalic gigantism, revealed a lack of the frontal sinuses, and a marked decrease in size of the sphenoidal and molar sinuses. The absence of one of the frontal sinuses, however, has been observed also in normal individuals, according to Nylen, in 5 per cent of 2,000 cases examined

In the epiphyses of the femora, tibia, and humerus, a small area of rarefaction and a diminished compactness of the trabeculae were encountered, whereas there was increase in the thickness of the diaphyses

Regarding the mandibles, it was found that lengthening of the lower jaw-bone may come about in two ways. In the first there may be lengthening without modification of the mental mandible angle, in the other, the angle assumes an amplitude quite disproportionate. While in the first case there are only very

slight modifications of the two mandible branches, in the second case there are changes in the marginal faces and, more characteristic, modifications of the coronoid apophysis, condyle, sigmoid incisure, and their connections. These modifications, the author believes, are seen relatively early in connection with other skeletal manifestations and may furnish an element in the radiologic diagnosis of acromegalia and acromegalic gigantism

W W WHITELOCK, Ph D

Supernumerary Tarsal Bones Valentín C Girardi Prensa Méd Argentina, Aug 20, 1931, XVIII, 360-364

The author gives a good review of this subject and concludes that of such bones the most common are (1) The accessory scaphoid, (2) the accessory cuboid, (3) the os trigonum, and (4) the os vesalianum pedis. The advent of X-ray has brought with it a more complete knowledge of such bones, which is important because of their medico-legal and surgical interest. In adolescence they may present inflammatory processes resembling those present in epiphysis of growing people. They may present total or partial fractures

N G GONZALEZ, M D

Fractures of the Pelvis Everett O Jones and H T Buckner Northwest Med., June, 1931, XXX, 269-273

Authors have described as many as ten different types of fractured pelvis, all of which can be covered by three main classes (1) fractures of the wing of the ilium, (2) fractures of the acetabulum, (3) fractures of the pelvic ring. Fractures of the iliac wing are always the result of lateral compression, the forcing being too high to strike the pelvic ring. Fractures of the acetabulum result from a direct blow on the greater trochanter, when the force is delivered exactly parallel with the long axis of the femoral neck, the acetabulum will yield, a force at any angle to this axis will break the neck of the femur. Fractures anywhere in the pelvic ring result from lateral compression, when forcibly com-

pressed from opposite sides, the breaking points will be somewhere near the intermediate poles. This principle holds, whether there be simply one or more fractures of the rami or the complete double fracture of Malgaigne. In the first place, the lateral compression produces a fracture or fractures about the anterior pole and a distortion or rupture of the sacro-iliac articulation at the opposite pole. This is frequently not disclosed by the roentgenogram and is not discovered until the patient begins to get about. It is a very important factor in the production of disability following this type of injury.

W W WATKINS, M D

BONE (THERAPY)

The Pathology and Treatment of Colles' Fracture M Cole Rous Jour Med Assn South Africa, Sept 26, 1931, V, 593-596

Colles' fracture is caused by a fall on the outstretched hand, in such a manner that the forearm makes an angle of 60 degrees or less with the horizontal. The line of the fracture is oblique and runs from in front backward and upward. The lower fragment is displaced dorsally, proximally, and rotated backward around a horizontal axis. The stability of the wrist is preserved by the ulna alone, the distal end of which is attached to the radius by the triangular cartilaginous disk, and its styloid process is anchored to the medial aspect of the carpus by the collateral ligament. The distal fragment of the radius tends to become displaced proximally, but is held on its medial side by the cartilaginous disk and the ulna, and this serves as an anteroposterior axis passing through the ulnar attachment of the disk, around which the distal fragment swings. As the distal fragment and carpus are carried around this axis, a great strain is thrown on the medial collateral ligament and the styloid process of the ulna to which it is attached. It is this force which frequently fractures the ulnar styloid.

Every case presenting a painful wrist and a history of a fall on the outstretched hand should have a thorough examination. It is im-

portant to observe the relative positions of the styloid, remembering that this process of the radius is normally situated slightly distal to that of the ulna. While the normal radius presents a concavity just proximal to where the pulse is palpated, in this type of fracture this depression is filled by the distal end of the proximal fragment of the fractured radius. The comparison of the uninjured with the injured wrist is considered essential by the author. The X-ray examination is invaluable to show clearly the amount of displacement and to exclude or discover the presence of other injuries to the bones.

The anesthetic which is essential for proper reduction of the fracture may be either local or general. Lorenz Bohler, of Vienna, favors the former—has used it with success in 4,000 cases. In the reduction of this fracture the author favors his method of employing counter traction by means of a canvas strip passed around the lower extremity of the humerus, with the patient's elbow flexed to a right-angle. This allows the operator to use both hands in the reduction. The best and most satisfactory guide in the reduction is the X-ray, and whenever possible the reduction should be done under the fluoroscopic screen. The author believes it is better to see what one is doing in the darkness of an X-ray room than to work blindly by the light of day. A plaster splint molded to the patient's forearm is employed to hold the fragments in place. Roentgenograms should then be made as a final check for the position of the fragments.

J N ANÉ, M D

Operative Treatment of Y-shaped Fractures of the Lower Extremity of the Humerus Terencio Gioia Semana Méd, Nov 6, 1930, XXXVII, 1407-1409

As this fracture is rare and exceedingly difficult to reduce, the author reviews it in detail in this article. He presents the serious factors confronted, such as (1) difficulty in reduction, (2) traumatic arthritis, (3) exuberant periostic proliferation, (4) Volkman's contracture, and (5) nervous complications. He presents a case with a typical Y-shaped

pendently of the region irradiated Man showed changes of the same nature under hepatic or splenic irradiation, corresponding to one S E D at the surface, a dose of one-half S E D causing no appreciable change

The effects were detected two hours after treatment and remained unchanged or slightly weaker for two days, at which time they started to decrease rapidly and disappeared after ninety-six hours

The author ventures the hypothesis that the increase of catalase content in the blood is a manifestation of the destructive action of the radiation on the cells of the body

L MARINELLI

BONE (DIAGNOSIS)

Certain Radiographic Peculiarities in the Skeleton of an Acromegalic Giant E Forlini L'Ateneo Parmense, January-February, 1931, III, 5-16

This article treats of the radiographic examination of the cranium and other parts of the skeleton of a female acromegalic giant who died of pulmonary and intestinal tuberculous ulcers, in 1889, at the age of thirty-one

The author's investigations, contrary to previous belief regarding acromegalia and acromegalic gigantism, revealed a lack of the frontal sinuses, and a marked decrease in size of the sphenoidal and molar sinuses. The absence of one of the frontal sinuses, however, has been observed also in normal individuals, according to Nylen, in 5 per cent of 2,000 cases examined

In the epiphyses of the femora, tibia, and humerus, a small area of rarefaction and a diminished compactness of the trabeculae were encountered, whereas there was increase in the thickness of the diaphyses

Regarding the mandibles, it was found that lengthening of the lower jaw-bone may come about in two ways. In the first there may be lengthening without modification of the mental-mandible angle, in the other, the angle assumes an amplitude quite disproportionate. While in the first case there are only very

slight modifications of the two mandibular branches, in the second case there are changes in the marginal faces and, more characteristic, modifications of the coronoid apophysis, cor-dyle, sigmoid incisure, and their connections. These modifications, the author believes, are seen relatively early in connection with other skeletal manifestations and may furnish an element in the radiologic diagnosis of acromegalia and acromegalic gigantism

N G GONZALEZ, M D

Fractures of the Pelvis Everett O Jones and H T Buckner Northwest Med., June, 1931, XXX, 269-273

Authors have described as many as ten different types of fractured pelvis, all of which can be covered by three main classes (1) fractures of the wing of the ilium, (2) fractures of the acetabulum, (3) fractures of the pelvic ring. Fractures of the iliac wing are always the result of lateral compression, the forcing being too high to strike the pelvic ring. Fractures of the acetabulum result from a direct blow on the greater trochanter, when the force is delivered exactly parallel with the long axis of the femoral neck, the acetabulum will yield, a force at any angle to this axis will break the neck of the femur. Fractures anywhere in the pelvic ring result from lateral compression, when forcibly com-

of the lip and of the vulva is not a syphilitic affection. Leukoplakia of the vulva is probably related to cessation of ovarian function.

Chronic inflammatory and obstructive lesions are associated with leukoplakia of the urinary tract.

Quoting from Lane-Claypon, a close association is shown between leukoplakia and cancer. The sex-incidence is similar, both preponderant in males (leukoplakia 95.8 per cent, carcinoma 90.2 per cent). Perrin's figures, quoted by Lane-Claypon, show 64 syphilitic leukoplakia buccalis with 10 carcinomas of the tongue, and 38 non-syphilitic leukoplakia buccalis with 9 carcinomas of the tongue.

The evidence for an association between leukoplakia and carcinoma of the esophagus is extremely slight.

Leukoplakia vulvæ is an accepted precancerous lesion, although here again it is impossible to get reliable figures. Berkeley and Bonney, in reporting their personal experience of 58 cases of carcinoma vulvæ, state that they have not yet seen a case in which leukoplakia did not co-exist. Taussig, in a series of 76 cases of cancer of the vulva, noted leukoplakia in thirty-nine. Carcinoma vulvæ is more frequently multiple in origin than any of the commoner forms of malignant disease.

The relation between leukoplakia and cancer of the cervix is less securely founded, and the total available evidence is scanty and unconvincing.

In the urinary tract also the evidence for an association between leukoplakia and cancer is inadequate.

It is concluded, therefore, that leukoplakia linguae and leukoplakia vulvæ are definitely precancerous lesions, the former usually but not always due to syphilis, with heavy smoking and drinking as auxiliary factors. So far as the esophagus, larynx, cervix uteri, and urinary tract are concerned, an association between leukoplakia and cancer is still unproved.

One of the remarkable features of cancer of the lip is the great difference in its incidence in the two sexes. Of 4,839 cases, 93.5 per cent occurred in males. Another point is the low incidence of cancer of the upper lip,

only 5.8 per cent of a series of 3,763 cases. Nearly one-fourth of all cases in women occur on the upper lip. It is believed that the unglazed clay pipe may cause such chronic burning of the lower lip as to lead to cancer.

The importance of prolonged exposure in the open air is stressed by some who find that laborers, merchant seamen, and outdoor railwaymen have an incidence of 200 or 300 per cent in excess of what might be expected. Open-air workers have unrestricted opportunities for smoking, and it is mentioned that the coal-miners working below ground, where smoking is forbidden, contrast with those working above ground in not suffering from excess of lip cancer.

In certain districts of India and the East betel-nut chewing is a widespread habit, and the incidence of carcinoma of the cheek is extraordinarily high. The betel "quid" is carried in the mouth just opposite the molars, which causes inflammatory thickening and roughening of the mucosa, leukoplakia, and epithelial denudation, followed by progressive ulceration.

Primary carcinoma of the liver is a rare disease in the white-skinned races. In 12,800 autopsies there were only 14 certain cases, or 0.11 per cent. Similar figures have been recorded by other observers. Chinese and Japanese compared to English and American whites have an incidence of 2.21 and 2.18 per cent. Among 91 carcinomas in South African natives, 36 primary cancers of the liver were reported. The hepatic cirrhosis of schistosomiasis has been regarded as a possible factor, and in China, infestation by another fluke has been regarded as a possible factor. Native inhabitants of tropical countries may have repeated and chronic affections of the sources of the portal vein, and this may play a part in the etiology of cirrhosis and cancer of the liver.

There are two main varieties of hepatic carcinoma, the hepatoma and the cholangioma. Liver-cell carcinoma is the commoner.

That cirrhosis of the liver is a precancerous condition is now generally accepted, and the support of this belief comes from figures showing a high incidence of cirrhosis in cases

fracture on which he resorted to surgery, doing a permanent osteosynthesis with wire. His conclusion is that the best treatment in such fractures is the operative one.

N G GONZALEZ, M D

BONE DISEASES (DIAGNOSIS)

Osteomyelitis of Gonococcus Origin in an Infant Report of a Case Philip Palew Am Jour Surg., August, 1931, XIII, 246, 247

The author reports a case of osteomyelitis of gonococcus origin. While a blood stream infection obviously was present, the original portal of entry for the organism could not be determined. X-ray films of the lesion accompany the report.

DAVIS H PARDOLL, M D

A Case of Co-existence of Congenital Luxation of the Ilium and Coxa Varo Gabriele Sacerdote Minerva Med., Apr 21, 1921, XXII, 614, 615

This article is a complete report of the clinical and radiologic findings obtained on a girl four and one-half years old.

Clinical examination revealed protruding trochanters, free movements with the exception of limited abduction of the left thigh. The head of the left femur was palpable under the femoral artery, the right seeming not to be in place. The spino-malleolar distance was 46 cm on the right and 45 cm on the left side, the greater trochanter was 5 cm on the left and 6 cm on the right above Roser-Nelaton's line. Trendelenburg's sign was positive in both sides.

The radiologic examination disclosed iliac luxation at the right and coxa vara at the left. The axis of the femur was at right angles with the axis of the diaphysis. The epiphyseal line was irregular and too vertical to be considered normal, as it formed an angle of 12 degrees with the diaphysis, at its lower third portion it seemed split, both branches surrounding an inverted wedge-shaped nu-

cleus. Surgical intervention was completely successful in correcting both defects.

The author mentions the very few cases described in the literature and insists upon the importance of determining the nature of the defect, because, while rickety anomalies of this kind improve with age, congenital ones tend to get worse and more difficult to correct.

L MARINELLI

CANCER (DIAGNOSIS)

Precancerous Lesions of the Alimentary Tract Lecture I Matthew J Stewart. Lancet, Sept 12, 1931, CCXXI, 565-572

The author in the Croonian Lectures delivered before the Royal College of Physicians of London on June 4, 9, and 11, 1931, states that of 56,896 deaths from cancer registered in England and Wales for the year 1929, 60 per cent in men and 42 per cent in women were referable to the alimentary tract. The most hopeful side of cancer research is that concerned with the demonstration of local causative factors and the recognition and prevention of precancerous lesions. The precancerous lesions of the alimentary tract are by no means so well established, nor are there the same opportunities for prophylaxis afforded as in the superficial forms of malignant disease.

The alleged precancerous lesions of the various portions of the alimentary tract are discussed under the following classifications:

(a) Chronic inflammatory lesions (1) Leukoplakia, (2) lesions due to burns and chemical caustics, (3) cirrhosis of the liver, (4) hemochromatosis, (5) cholelithiasis and cholecystitis, (6) chronic gastric ulcer, (7) chronic gastritis, (8) chronic duodenal ulcer, (9) diverticulitis.

(b) Simple tumors as precursors of cancer

(c) Lesions due to animal parasites

The etiology of leukoplakia is different for different sites. In the mouth, syphilis is the chief cause. Excessive use of alcohol and tobacco were also given as causes. Leukoplakia

cancer of the alimentary tract in man. There is, however, experimental evidence of such in animals. In inhabitants of Egypt there is a high incidence of bladder carcinoma and a closely associated schistosomiasis.

The author stresses the importance of local factors in the etiology of malignant disease, the need of statistical information of racial and geographic incidence of cancer, and study of the environmental factors of the human race.

F. L. GRANDSTAFF, M.D.

The Combined Electrocoagulation-radium Treatment of Skin Carcinoma Anton Musger *Strahlentherapie*, Sept 12, 1931, XLII, 143-147

In 50 cases of skin carcinoma (20 on the nose, 11 on the cheek, 4 in the frontal region, 4 on the lower lip, 3 in the temporal region, 3 in the helix, and 5 on the arm) combined treatment by the endotherm method and radium was carried out. All carcinomatous tissue was first removed and treated by radium immediately, or the next day. Suberythematous doses of from 70 to 80 per cent H.E.D. were applied from 5 to 8 times at intervals of from one to two days. If necessary, this series was repeated from 6 to 8 weeks later. After complete healing of the lesion one or two prophylactic treatments were added.

The end-results of this method were so encouraging that it is recommended as the method of choice. One great advantage of the procedure is the fact that it shortens the treatment period considerably.

ERNST A. POHLE, M.D., Ph.D.

Primary Carcinoma of Bronchus E. E. Atkin *Jour Path and Bacteriol*, May, 1931, XXXIV, 343-448

This study deals with the postmortem findings of 93 cases of primary carcinoma of the bronchus. Of these, 80 were in men and 13 in women.

Microscopically the appearance of the cells varies greatly in different growths and even in the same growth, and there are all stages in

the change from the ordinary columnar to the typical squamous cells. The squamous-cell type exhibits a great tendency to necrosis and cavity formation.

Secondary deposits in the lung not affected by the primary growth are uncommon, but in certain cases in which these did occur the author found it difficult to avoid the conclusion that the spread had been by aspiration via the bronchi. He found that carcinoma does not appear to arise more frequently in one bronchus than in the other.

Metastases to the abdominal organs occur in the following order of frequency: None, 47; liver, 23; pancreas, 18; kidneys, 14; suprarenals, 12; spleen, 4.

E. C. VOGT, M.D.

CANCER (THERAPY)

The Treatment of Carcinoma of the Cervix Uteri A. L. Mudaliar *Antiseptic*, July, 1931, XXVIII, 499-505

In the treatment of carcinoma of the cervix uteri the following methods are now employed: (1) Operation, (2) irradiation with X-ray, radium, or both, (3) irradiation and operation. The question of operability is always subject to a diversity of opinions. While at first radiation therapy offered disappointing results in the treatment of these cases, with improved technic and more clinical experience the results have been more satisfactory.

The author briefly discusses the Heyman, Brussels, Paris, and St. Bart's methods of applying radium to the cervix and vagina. He believes that it is advisable to order vaginal douches before and after the application and in those cases in which the radium is left in place for several days. The removal of the radium should be followed by a cleansing douche daily. Manipulation and curettage are not advised in these cases. In the case of the cauliflower growths the cautery has been found useful in removing exuberant tissue.

The contra-indications to irradiation discussed by the author are as follows: Anemia, with a red cell count below 3,000,000; general

of primary cancer, and comparative infrequency of primary carcinoma in non-cirrhotic livers

The author shows that carcinoma occurring in a cirrhotic liver is the end-stage of a well-recognized series of pathologic changes

Sarcoma of the liver is extremely rare, but there is a certain association of sarcoma of the liver with cirrhosis of the liver

The author, in discussing hemochromatosis, referred to Rolleston and McNee as to etiology, and in the author's series of cases all 13 showed cirrhosis of the liver

The author states that, when recognizable, hemochromatosis is invariably accompanied by some degree of hepatic cirrhosis, and might, therefore, be expected to have an association with primary carcinoma of the liver

After a thorough study of collected series of cases, it is not found possible to attach any significance to the apparently high rate of incidence of primary carcinoma of the liver in hemochromatosis, and the causative factor in both groups is the cirrhosis

The article is accompanied by numerous tabulations of statistical material

F L GRANDSTAFF, M D

Precancerous Lesions of the Alimentary Tract Lecture II Cholelithiasis and Cholecystitis Matthew J Stewart Lancet, Sept 19, 1931, CCXXI, 617-622

Continuing the Croonian Lectures, the author shows close association between cholelithiasis, cholecystitis, and carcinoma of the biliary passages. In 43 cases of the gall bladder, there were 30 with gallstones, or 69.8 per cent, as compared with 16.4 per cent in a control series of 1,031 gallstone cases in 6,284 autopsies. It was found that carcinoma occurred more frequently when the gallstones were multiple and faceted.

Leitch was able to produce carcinoma experimentally by inserting gallstones into guinea pigs' gall bladders.

Gastric ulcer and its relation to carcinoma is discussed at length. After careful consideration of morbid anatomy and histology, site

of the lesion, gastric analyses, and clinical history, it was not possible to state, with any degree of certainty, what proportion of chronic ulcers became malignant. The number is probably small, however, of 109 surgical specimens of carcinoma of the stomach, 17, or 15.6 per cent, showed evidence of having originated in a pre-existing simple ulcer.

In the author's experience, a chronic gastritis of the lesser curvature and pyloric region was common in cases of gastric ulcer, and less common in cases of carcinoma. Gastritis is believed to be a real precancerous lesion, but how often it progresses to malignancy cannot be stated. Chronic duodenal ulcer could not be considered a precancerous lesion, after reviewing the literature and bearing in mind the frequency of chronic ulceration. Carcinoma of the duodenum, in most cases, arises in the peri-ampullary portion, and it is not always possible to determine whether it had its origin in the duodenal mucosa or in the ampulla of Vater.

It was concluded, after reviewing the literature, that diverticulitis has no practical importance as a precancerous lesion.

Carcinoid tumor of the appendix and its association with old inflammatory disease of the appendix is well established. It rarely occurs in the small intestine and when it does so, it is usually multiple.

The lecture is accompanied by numerous statistical tabulations.

F L GRANDSTAFF, M D

Precancerous Lesions of the Alimentary Tract.—Lecture III Benign Tumors as Precursors of Cancer Matthew J Stewart Lancet, Sept. 26, 1931, CCXXI, 669-675

Concluding the Croonian Lectures, the author states that the outstanding example of benign precursor of precancerous lesions in the alimentary tract is the adenomatous polypus of the stomach, colon, and rectum, and the rare condition of "polyposis intestini." There is no evidence that heterotopic tumors are particularly liable to malignant change.

There is scanty evidence of a connection between infestation by animal parasites and

tory function is antagonistic to radiosensitivity. These facts partly explain the differences in behavior of cancers of the same localization and sometimes of the same origin.

Perfectly selective radiotherapy makes use of a favorable interval between the radiosensitivity of the cancerous tissue and those of the normal tissues, both general and special.

There is a very extensive scale of differences of radiosensitivity among malignant neoplasms. The radiosensitivity of a neoplasm can be artificially modified. The intervention of the time factor diminishes or increases the interval between the degrees of radiosensitivity.

When radiotherapy is fractionated and spread out over a very long time, the interval between the degrees of radiosensitivity is diminished, then suppressed and reversed.

When radiotherapy is fractionated and spread out over a moderate time, there is an increase in the interval between the degrees of radiosensitivity between the general tissues and certain special normal tissues which have rapid renewal (for example, seminal epithelium).

Cancerous tissues behave as does seminal epithelium. From this fact follows the abolition of the massive dose for curietherapy and roentgentherapy of epidermoid cancers at the Radium Institute of Paris.

Between perfectly selective radiotherapy and diffusely caustic radiotherapy, there are intermediate stages which may be used in certain determined conditions.

B J DE LAUREAL, M D

Review of the Results Obtained Hitherto by my Cure in Cancerous Patients S
Citelli Minerva Med., June 9, 1931, XXII,
861-865

The author advocates the treatment of tumors by subcutaneous injections of extract of the patient's tumor. Such treatment was started in 1914, and the author recalls the various reports he has since presented. He discusses his results at length and compares them with Fichera's, emphasizing the fact that their methods differ widely in principle, although

histologic examination ultimately reveals very similar action on neoplastic growths.

L MARINELLI

Radium and X-ray Therapy in Carcinoma of the Larynx A Gunsett Le Cancer, 1930, VII, 61-82

This paper is a report on 34 cases, most of which were treated by X-rays, but in the advanced cases radium was applied, either alone or in addition to the X-rays. Hard rays were used, the secondary voltage being 200 K V, and the filtration not less than 1 mm of copper. In the later cases the filter was 2 mm of copper.

The author attaches great importance to the quality of the ray, and states that prior to 1921, when he used a kilovoltage of only 120, with a filter of 5 mm of aluminum, he had never seen a patient with cancer of the larynx survive longer than a year after treatment. Another technical point which is emphasized is the time over which the treatment is extended. A period of about from 15 to 21 days is recommended. Two lateral fields were employed, each 150 sq cm in size, the anti-cathode-skin distance being 40 centimeters. The dose applied to each field was from 2,200 to 2,500 r. The radium was applied on a moulded apparatus at a distance of 4 cm and filtered by 2 mm of platinum. In a few cases needles also were inserted. Of the 34 cases, 10 were intrinsic carcinomas, four of which are reported as cured—one for eight years, one for six years, and two for over three years.

In none of these cases were enlarged glands palpable in the neck. The remaining 24 cases were extrinsic growths, of which four cures of at least three years' duration were obtained. Of these, one remained well for five years and then suffered a recurrence recently. The extrinsic cases were all very advanced and with extensive glandular involvement. It is in these cases that the author recommends radium therapy by external methods, and he gives it as his opinion that only temporary results can be obtained in them by X-ray therapy alone.

WALTER M LEVITT, M R C P, D M R E

emaciation and cachexia, impaired nitrogen metabolism, because radiation tends to increase the blood nitrogen, the presence of inflammatory lesions, complications in the urinary and renal tracts, amenorrhea, and pregnancy. The author believes that Indian patients do not endure large doses of radium as well as Continentals do.

J N ANÉ, M D

Carcinoma Therapy with Extremely Hard Roentgen Rays Erich v Schubert Strahlentherapie, Sept 12, 1931, XLII, 136-142

In this article the author describes the gamma volt apparatus which has been installed in the Women's Clinic of the University of Berlin. The transformer is built for a maximum output of 600 KV, but only 400 KV and 1 ma are practical, as it is not possible to run tubes at higher potentials. As filters, 2 mm of Cu and 2 mm Al are used at 66 cm distance, the output being 32 r per minute. A number of illustrations show the arrangement of the apparatus and tube. The latter is placed in a room below the treatment room. The patient lies in a lead box which affords ample protection. The ceiling and walls of the apparatus room are covered by 15 mm of lead. Fans and electric heaters keep the humidity in the engine room from 30 to 40 per cent. After the application of 3,000 r over a single area within 20 days there appears, about five days after the last exposure, a dark red discoloration and intense pigmentation of the skin, followed by necrosis of the epidermis in large pieces. A healthy looking subepithelial layer covered by epidermis appears within 14 days. During the reaction there is moderate pain in the skin. If 4,000 r were applied within 14 days a similar reaction appeared. In spite of the fact that the treatment was given over the lower part of the abdomen there was no irritation of the bladder or the intestines. The leukocytes dropped considerably, particularly the lymphocytes, and there was a marked effect on the tumor.

In closing, the author believes that this expensive and complicated apparatus should be

used only in advanced cases with involvement of the parametrium which are treated in other countries by the so-called radium bomb.

ERNST A POHLE, M D, Ph D

Radiation Therapy of Carcinoma of the Rectum Ira I Kaplan. Jour Am. Med. Assn., Oct 3, 1931, XCVII, 991-994

Carcinoma of the rectum constitutes one of the most interesting studies for the radiation therapist, because when a patient suffering from this condition is sent for irradiation, it is usually with a gesture of despair, since the results from treatment of every kind have not been too encouraging.

Cancers of the rectum constitute one-third of all the cancers affecting the body. Rectal cancers stand third in the list of cancers of the intestine causing death. To a limited extent and in a chosen group of cases, surgery offers a very good chance for cure. Usually those referred for irradiation are inoperable. Irradiation can be carried on without colostomy.

A newer method, based on the Regaud principle of small doses of radium applied over a long period of time, is described for applying radium to rectal lesions. A special applicator for the method is also described.

C G SUTHERLAND, M B (Tor)

On the Radiophysiology of the Radiotherapy of Cancer Cl Regaud Arch. Radium Institute, University of Paris and Curie Foundation, 1931, II, Part 3, 319-357

Normal tissues and tissues of human cancers have a common radiophysiology.

There are two kinds of action by rays on mixed tissues:

(1) By direct, violent, and relatively short attack on the most sensitive of their cellular varieties (method of cure of malignant tumors),

(2) By progressive modification of the vasculo-connective stroma (palliative treatment of cancers, treatment of chronic inflammations).

Radiosensitivity is dependent on the multiplication of the germinative cells. Secre-

, the experiments undertaken for establishing an accurate physical foundation. The apparatus used, including measuring instruments, is described in detail. The cathode-ray tube furnished by Muller was operated on a vacuum pump and tolerated potentials up to 220 KV at 4 ma, if the window was well air-cooled. Since the article is rather technical, it may suffice to mention some of the conclusions reached by the author.

He developed a graphic method to determine the speed of the cathode rays outside of the tube. In order to characterize the velocity spectrum of a heterogenous cathode ray beam, he introduces the term "effective velocity" and also describes the method for its determination. A comparison of the figures obtained by that method shows good agreement with the figures published by Lenard. An ionization instrument is also described which permits the determination of the practical length of path of the electrons. The law of Schonland, stating that the product of practical length of path and density is constant for several metals, holds also for air. According to the author's measurements the constant for air used in Widdington's equation is too high, while Wilson's equation agrees well with his own figures. He constructed a concentration coil for cathode rays which permits an increase of the surface intensity of cathode rays in the central ray. Experiments were carried out with this arrangement in order to differentiate the effect of the cathode rays proper and the roentgen rays produced at the tube window. It appeared from exposures of tryptophan solutions that the part destroyed by X-rays was 219 times greater than that destroyed by the cathode rays. This shows that the effect of the X-rays produced at the tube window is greater than that of the cathode rays proper. The author also outlines a method which enables one to study the intensity of X-rays produced by cathode rays on various anti-cathodes.

CONTRAST MEDIA

Researches upon the Opaque Medium Most Innocuous in Arteriography Guido

Oselladore Minerva Med , Sept 22, 1930, XXI, 410

The author has compared the effects of a 25 per cent solution of sodium iodide with those of a 40 per cent solution of uroselectan. The tests were performed on animals and under various experimental conditions. Histologic investigation showed that while uroselectan is perfectly harmless in all cases, sodium iodide produces a definitely harmful action on the capillary system and on the adjacent tissues, especially when circulation of the blood is greatly impaired.

The importance of arteriography in cases of gangrene is illustrated by a clinical example in which radiography very neatly determined the limits of arterial occlusion. The radiologic findings were fully confirmed by dissection.

L MARINELLI

The Usefulness of the Different Contrast Media for Intravenous Pyelography A Beutel Med Klinik, Aug 21, 1931, XXVII, 1240, 1241

Three contrast media for intravenous pyelography have been used by the author and he endeavors to evaluate their use. Pyelognost (Roseno), an iodine-urea combination, was tried in eight cases but its use was soon discontinued on account of the lack of contrast and undesirable symptomatic effects. Uroselectan (Binz, Rath, Swick, and von Lichtenberg) was used in 51 intravenous pyelograms. Abrodil (Ossenbeck and Tietze), called "skiodan" in the United States, was also used in 51 cases. Comparison of the results of uroselectan and abrodil showed that both gave satisfactory contrast. Although the price of both drugs is the same, the use of abrodil is less expensive as only one film had to be taken in over half of the cases, whereas, with uroselectan, the pyelograms almost always required two and even three films. The time of preparation and injection is considerably shorter with abrodil. There appeared less reactions from abrodil than from uroselectan. Of the contrast media

The Relative Value of Irradiation and Operation in the Cure of Uterine Cancer
John Osborn Polak Ohio St Med Jour,
May, 1931, XXVII, 363-366

This is one of Dr Polak's last papers, being the Gilliam Memorial Address before the Columbus Academy of Medicine, on Nov 17, 1930

There is still confusion in the mind of the practitioner as to what should be done in the particular case of cervical cancer which he observes. The operable group constitutes only about 10 per cent of the total number of cases seen. By "operable case" is meant one with a growth which is entirely within the confines of the cervix, the uterus being movable, with no detectable parametrial involvement. The other 90 per cent are not operable, can only be treated by irradiation, and do not come into competition with surgery.

"We may state that the superiority of radium over surgery in the treatment of cervical cancer is now generally recognized by surgeon and gynecologist all over the world, with the exception of the three men mentioned in this review (Weibel, Adler, and Bonney), for, if carcinoma of the cervix is diagnosed in its earliest stages, and radium treatment properly administered, it is possible to cure from 50 to 66 per cent of the cases. Surgical treatment of cervical cancer should be virtually abandoned since better results can be obtained by irradiation and X-ray therapy. The woman is better off with no operation than she is with an incomplete one. In early body cancer her best chance lies in radical operation followed by deep X-ray irradiation."

W W WATKINS, M D

The Treatment of Metastatic Involvement of the Neck Secondary to Intra-oral Cancer
Orville N Meland Am Jour Roentgenol and Rad Ther, July, 1931, XXVI, 20-22

It is emphasized that all enlarged cervical nodes found co-existing with intra-oral cancer are not necessarily malignant, hence, needling or other form of biopsy is at times necessary to establish the fact of gland extension. In intra-oral malignancies, the author

divides his cases for gland treatment into three groups

Group 1 consists of cases given prophylactic radiation in which no regional metastases can be demonstrated. These patients are given high voltage X-radiation pushed to the point of saturation on the side where metastasis might be expected, with half the dose on the opposite side. If radium is used, it is in the form of a pack, filtered through one millimeter of brass at three centimeters' distance for a total of 6,000 milligram-hours. Group 2 is the surgical group, showing one or more movable, intact, unilateral nodes which are surgically removable. These are first given a thorough course of X-radiation over a period of from three to four weeks, then if no regression takes place, they are given either a radium pack, or electro-surgery is used. If electro-surgical removal of the nodes is done, the edges of the wound are planted with radium needles. Occasionally with only a single node involved, blind needling is done, but this is considered a relatively inaccurate method as compared with electro-surgical exposure. Group 3 is the palliative group which is treated mildly by irradiation to retard progress of the disease, relieve pain, and prevent rapid breaking down of primary or metastatic masses.

CATHODE RAYS

Investigations Concerning the Biologic Effects of Cathode Rays I—Introduction
B Rajewsky Strahlentherapie, Sept 12, 1931, XLII, 1-5

II—The Physical Properties of the Radiation Emitted by a Lenard-Coolidge Tube
W Gentner Strahlentherapie, Sept 12, 1931, XLII, 6-55

Rajewsky states that the data published so far concerning the biologic effect of cathode rays are not comparable. This is due to the fact that no qualitative and quantitative measurements were carried out. A systematic study of the problem, therefore, seems indicated.

Gentner presents the first part of the study,

the sympathetic. At first there is a fall of basal metabolism and then an increase. During the fall, the organism does not react to a fresh diathermic application. The application should only be renewed when the effects of a previous one have passed off. The variations of basal metabolism are not parallel to the modifications of other symptoms or to variations of the subjective state of the invalid.

CHEMICAL ABSTRACTS

Diathermy in Acute Inflammatory Conditions B N C Roy Antiseptic, July, 1931, XXVIII, 540-544

The high voltage used in diathermy results in the current passing along a direct path between electrodes. Those tissues which are situated between the electrodes are heated so rapidly that it is impossible for the circulatory system to equalize the temperature immediately. An acute temporary dilatation of capillaries occurs which results in acceleration of the circulation of the blood in the deeper tissues. This facilitates the cellular interchange of gases and fluids and an increase in local resistance. The temporary dilatation is followed by contraction, which restores the tone to lymphatics and capillaries. Diathermy raises the body temperature to some extent and lowers both systolic and diastolic blood pressures.

We depend upon the leukocytes and the immune bodies for a healing process. Anything which helps in attracting and concentrating these agencies in the affected tissues will, therefore, aid in the healing. Consequently, what is required is some special means to make the area more approachable and permeable by the formation of new capillaries, allowing more passage of blood. Diathermy properly applied is believed by the author to accomplish this admirably.

J N ANE, M D

DOSAGE

The Diversity of Reactions of Tissues Treated by X-rays, Including the Time Fac-

tors and the Relations of the Dosimetric Biology in the Radiotherapy of Malignant Tumors Cl Regaud and R Ferroux Arch Radium Institute, University of Paris and Curie Foundation, 1931, II, Part 3, 293-318

Following considerable experimental work, the authors come to the following conclusions:

(1) The sterilization of seminal epithelium by X-rays, be it partial or total, is irreparable.

(2) It is impossible to sterilize the testis of the rabbit by a single irradiation, without the production of radiolesions of the skin, often fatal and always the cause of cachexia.

(3) The massive dose which causes severe radiolesions of the skin is between 4,000 and 4,400 Solomon R units.

(4) If the X-radiation is produced under high tension (180 K V), the changes of filtration between 0 and 8 mm of aluminum modify very little the relation between the ionometrical dose and the greatest biologic phenomena.

(5) When the distribution of the rays is spread out over a longer time, the threshold dose for radio-necrosis increases proportionately.

(6) On the contrary, the radiolesions of the seminal epithelium are not diminished by the lengthening—up to a certain limit—of the time of treatment, the doses remaining equal.

(7) This discordant behavior of the tissues allows the destruction of all the spermatogonia, with the production of serious lesions of the skin.

(8) For a dose of about 5,000 R the optimum arrangement of the time factor appears to be obtained by the equidistant distribution of four or five equal fractions in from four to nine days.

(9) Radiotherapy gains greater selectivity when the dose is fractionated and spread out.

(10) Is the dose necessary for sterilization increased, maintained, or diminished by being fractionated and spread out? This question remains unanswered.

(11) The analogy between the behavior of the germinative spermatogonia and certain cancerous tissues has led the Radium Institute of Paris to prefer, for the treatment of

available so far, abrodil (skiodan) appears to be more satisfactory in fulfilling the requirements

CYSTS

Congenital Cysts of the Lung A Dethmers Acta Radiologica, 1931, XII, No 66, 15, IV, 135-139

The author presents the case of a woman 34 years old who entered the hospital with a diagnosis of pulmonary tuberculosis. Her general health had always been good, in spite of a cough since the age of five years. She had worked without physical difficulty as a servant and in a factory. Because two sisters had developed pulmonary tuberculosis, she had had her chest examined in 1918. At that time the physician advised a rest cure at home. Unfortunately there was no roentgen examination on this occasion.

In 1920, she went through a normal pregnancy and delivery. In 1923, she had a laparotomy, with removal of one tube and anterior fixation of the uterus. In 1924, under spinal anesthesia, an ovarian cyst was removed. After these operations the patient regained her good general health. Up until the last year before her admission to the hospital she had not had any expectoration, but during this latter twelve months she began to raise sputum and had several febrile attacks resembling influenza. Dyspnea also had recently developed.

At the time of admission to the hospital her condition was as follows. No loss of weight or strength, appetite good, pulse and blood pressure normal, no fever, von Pirquet negative, Mantoux positive, Wassermann negative, complement fixation for echinococcus negative, about 60 c.c. of sputum daily, negative for tubercle bacilli. Chest examination showed tympanitic percussion note over the right upper lobe, bronchial breathing, large and moderately coarse râles over the same area.

Films of the chest showed that the whole upper right lobe was filled with irregular,

sharply outlined annular shadows, one of which presented a fluid level. The remainder of the chest appeared normal. Lipiodol was administered under fluoroscopic control. Films made at this time showed lipiodol in numerous cavities throughout the right upper lobe. Very fine reproductions of these two sets of chest films illustrate the article.

The author feels that there was no foundation at all for the diagnosis of pulmonary tuberculosis and that the history and negative laboratory findings rule out echinococcus cysts and bronchiectasis localized in the right upper lobe. He regards the case as one of congenital cysts of the lung and reviews briefly the cases reported in the literature, most of which have been diagnosed only at autopsy.

A L HART, M.D.

Suprahyoid Dermal Cyst Implanted in the External Auditory Meatus Atilio F Parodi Prensa Méd Argentina, Aug 20, 1931, XVIII, 359, 360

This case is here presented because of the unusual site of the cyst. Only one other case has been reported in the literature. The patient is a girl 14 years old, who, a few months after birth, presented a lump in the left submaxillary region. This remained about the same size until the first menstrual period, when it started growing rapidly. The cyst was injected with lipiodol and radiograms were taken. Finally, it was dissected *in toto*.

N G GONZALEZ, M D

DIATHERMY

Influence of Diathermy of the Thyroid Gland on Basal Metabolism J Jankowski and L Ptaszek Compt rend soc de biol, 1930, CIII, 425-427, Physiol Abstracts, XV, 315

Diathermic treatment of the thyroid gland caused an increase of basal metabolism which was parallel to the improvement of symptoms. The reaction of the organism to this stimulus has the character of an endocrino-vegetative reflex. In the first phase there is excitation of

pencil These varices are covered by only a thin layer of connective tissue Their danger lies in their tendency to bleed The upper esophagus may be affected similarly in obstruction of the superior vena cava

There are three important causes of portal obstruction with varicosities in the esophagus (1) Cirrhosis of the liver, (2) syphilis of the liver, (3) portal thrombosis The clinical diagnosis of esophageal varices is extremely difficult The patients have usually been thought to have peptic ulcer Only a few cases diagnosed at roentgen examination have thus far been reported, but, no doubt, as the technic improves more cases will be found antemortem

The author reports the two following cases

A woman of 48 years had vomited blood on several occasions The clinical diagnosis was peptic ulcer Ordinary roentgen examination of the stomach showed medial displacement of the fundus and pars media by an enlarged spleen but no other pathologic changes in stomach or duodenum The esophagus was then examined with both thin and thick opaque material Films made while the barium mixture was passing through the lower esophagus showed semicircular filling defects irregularly scattered through the esophagus, while films made after the barium had passed into the stomach showed remnants of the opaque material lodged in the grooves and about the edges of the filling defects At autopsy large varicosities were found in the lower esophagus and the fundus of the stomach, and, in addition, cirrhosis of the liver, subacute hepatitis, and cholelithiasis

A man of 47 years had ascites Examination of the esophagus showed the same appearance as in the first case Autopsy was not obtained in this patient

A L HART, MD

THE ESOPHAGUS (THERAPY)

Surgical Treatment of Idiopathic Dilatation of the Esophagus Henri Oberthur Arch d mal de l'app digestif, June, 1931, XXI, 649-679

A simplified surgical procedure is offered for the relief of idiopathic lower esophageal

dilatation Two cases are presented, both permanently relieved by this benign and efficacious method which is a modification of Heller's and Wendel's methods It consists of an extra-mucus esophagoplasty through the upper abdominal route The left triangular ligament is cut, allowing more freedom to the liver and better exposure of the cardia The peritoneum is then cut at its reflection on the diaphragm and the esophagus The small omentum is split along the right side of the esophagus, exposing it and the diaphragmatic opening Posteriorly it is freed from the meso-esophagus with the fingers With curved closed scissors and tampons it is further freed from the diaphragmatic pillars and pulled down from eight to ten centimeters The muscularis is incised anteriorly and vertically beyond the entire length of the contracted area

Radiologically the results are perfect, the dilatation diminished considerably, and the passage of food unobstructed The etiology is discussed and the author believes the mechanism to be a primary dilatation rather than a congenital defect This is followed by local irritation and stasis, the contributing factors being insufficient mastication, poor dentition, alcoholism, spices, badly prepared and heavy foods This eventually leads to a cardiospasm and inflammatory stenosis Medical treatment has never cured a cardiospasm, and dilatation methods are frowned upon as being dangerous and giving but fair results

EXPERIMENTAL STUDIES

The Biologic Study of Radiosensitivity Part I—The Effect of X-rays upon the Immature Tissues of Plants J Nakagawa Japanese Jour Obstet and Gynecol, June, 1931, XIV, 218-224

Experiments have proved that small doses of X-rays stimulate germination, while large doses inhibit this function There is likewise some difference of opinion regarding the formation of X-ray tumors and the generation of monsters following strong irradiation Assuming that the process of the formation of

epidermoid cancers of all localizations, radiotherapy prolonged over a definite time to massive radiotherapy. The improvement of the therapeutic results has confirmed the correctness of this opinion.

(12) The biologic effects have no dosimetric significance independent of the time and can not serve to define absolute doses of radiation.

(13) The conclusions relative to the relations between the doses and the thresholds of biologic effects have validity only for the qualities of radiation which are effectively utilized.

B J DF LAUREAL, MD

The Fractional X-ray Dose H C Menkel Antiseptic, July, 1931, XXVIII, 523-525

Holzknecht, Sabouraud, Bordier, and others, for a considerable time, were in favor of the massive dose unit in the application of X-ray therapy. In the last few years, however, there has been some reversion to the smaller dose and more frequent exposures. Holzknecht definitely abandoned his advocated massive dose and adopted the fractional dose technic. Experimental work has shown that more striking results have been obtained in the destruction of malignant tissue by the use of smaller and more frequent doses than by the application of a single massive dose. It has also been shown in humans that tumors which no longer reacted did so when the dose was distributed over several days. The theory rests on the fact that division of cells ceases immediately after irradiation, this condition persisting for several days, when division again occurs. The cells at the time of division are particularly sensitive to the X-rays and if one is fortunate to again irradiate at the proper time, the effect is from two to three times as great as when the total dose is given in one sitting.

The author concludes that biologic experiments have indicated along what lines the future treatment of cancer should progress. There is no doubt but that X-rays produce results and that correct technic is essential, but it is the knowledge of the pathology

of cancer which will lead the way to the proper treatment of this disease. It should be remembered that cells are most susceptible to the influence of the X-rays at the stage of transition or mitosis. It is likewise essential to bear in mind that it is the absorbed rays which produce the desired therapeutic effects.

J N ANÉ, MD

THE ESOPHAGUS (DIAGNOSIS)

Epithelioma of the Esophagus in Association with Achalasia of the Cardia Geoffrey Rake *Lancet*, Sept 26, 1931, CCXXI, 682, 683

As a result of achalasia there is intermittent irritation of the esophagus. The condition of epithelial hyperplasia often occurs with production of definite papillomas. As irritation continues, these become malignant. In fifteen fatal cases, three deaths were due to malignant growths from ulcerated areas, resulting in cases of achalasia.

Prophylaxis consists of diet and a régime, as advised by Hurst, and emptying of the dilated esophageal sac by mercury bougie. Cases having papillomatous growths should have a periodic esophagoscopic examination.

F L GRANDSTAFF, MD

Roentgen Diagnosis of Varices in the Esophagus R Hjelm Acta Radiologica, 1931, XII, No 66, 15, IV, 146-151

The author first discusses the cause of esophageal varices. The portal vein drains the stomach, intestine, and spleen. Any obstruction in the portal vein causes congestion, which, in turn, results in dilatation of the anastomotic vessels. The collateral splenic veins are small and poorly developed, the most important of them coursing through the gastrosplenic and splenorenal ligaments and emptying into the lower esophageal veins. These esophageal veins also act as collaterals for the stomach veins. Hence, in portal obstruction these veins frequently become greatly enlarged, even reaching the size of a lead

In the group which had received medium irradiation the degenerative changes in the nuclei and swelling of the cell bodies were more marked. In the strongly irradiated group the swelling of the cell bodies was marked, those lying together appearing as if sutured, and the arrangement of the cells presented evidence of abnormality.

The degree of disturbance observed by the author in these experiments was not proportional to the amount of irradiation. This is explained by variations in sensitivity of the individual cells constituting the tissues in the seeds. In this experiment it was also observed that the deeper layer of cells was more markedly affected than the outer layer. This was due to the fact that the sensitivity to X-rays was greater in the deeper layer of cells, in which mitosis was more marked. It was noted also that the first evidence of the effects of irradiation was observed in the chromatin of the nucleus. The author believes that the abnormality in arrangement of the cells is not the immediate effect of irradiation but is secondary to the degenerative changes in the nucleus and cell-body, due to X-rays.

J N ANÉ, MD

Tumor Immunity The Effects of the Eu- and Pseudo-globulin Fractions of Anti-cancer Sera on Tissue Cultures Thomas Lumsden Jour Path and Bacteriol, May, 1931, XXXIV, 349-355

The author had previously developed an anti-cancer serum by inoculating cancer of one species (*e.g.*, man) into a heterologous animal (*e.g.*, sheep). When this was applied to tissue cultures of normal and malignant cells taken from an animal of yet another species (*e.g.*, mouse or rat), the malignant cells were killed in a few minutes while the normal cells survived and continued to grow. When, however, a sublethal dose of such serum was inoculated into the general circulation of a cancerous mouse or rat the cancer was little, if at all, affected. The reason for this was that the anti-cancer serum became too much diluted by the body fluids.

Only by stopping the circulation in the tu-

mor and injecting the serum was it possible to repeat *in vivo* the results obtained *in vitro*. After successful treatment of an implanted tumor, the cured animal became highly resistant to subsequent implantation of tumor cells.

It was later pointed out that the serum of an animal frequently inoculated with fragments of heterologous cancer contains three factors toxic to the cancer which was used as an antigen.

(1) Heterotoxin which is lethal to all heterologous cells. This is normally present in the serum of untreated animals.

(2) Anti-malignant-cell bodies having a specific affinity for cancer cells.

(3) Anti-species bodies lethal to normal as well as malignant cells of the species from which the cancer used as an antigen was taken.

By fractioning anti-cancer serum, the heterotoxins and anti-species bodies can be removed or destroyed, so that the resultant euglobulin fraction is ten times less toxic to mice, although it has lost none of its toxicity to the cancer cell.

It is considered that these experiments demonstrate beyond reasonable doubt the existence of anti-bodies having a specific affinity for cancer cells.

E C VOGT, MD

Comparative Investigations on the Effect of Bucky and Roentgen Rays on Cell Division G Politzer and J Zakovsky Strahlentherapie, Sept 12, 1931, XLII, 165-170

Salamander larvæ, about fourteen days old, were placed in small glass dishes on moist filter paper. Then the larvæ were exposed to Grenz rays at 10 cm distance. Every three minutes they were rinsed in cold water in order to prevent changes due to increased temperature. The tube was operated at 10 KV and 10 ma, the duration of exposure varying between five and twenty minutes. The output of the tube was 150 r per minute. Histologic studies of the irradiated larvæ

such conditions is better studied in the immature tissues of plants, the author irradiated the seeds of the *Vicia faba*. From $\frac{1}{3}$ E D to $6\frac{2}{3}$ E D were administered after the seeds had been steeped in water and sown in saw-dust. At a definite time following irradiation the seeds were fixed in paraffin and serial sections were made and examined. These were compared to normal non-irradiated seeds prepared in a similar manner.

The experimental results summarized were as follows:

(1) Strong and medium irradiation produced the same biologic changes.

(2) The development and growth of the root were disturbed and the tip had the appearance of permanent tissue.

(3) The most marked changes were observed at the vegetation point, which was abundant in immature cells, and which showed after irradiation many multinuclear giant cells.

(4) The earliest and most marked changes appeared in the nuclei of the cells, which showed the greatest swelling, shrinkage, and destruction from three to five days after irradiation.

(5) Mitosis was rarely observed and, when seen, appeared irregular and asymmetric.

(6) The changes in the cytoplasm were observed relatively later and consisted of the appearance of granules and large vacuoles.

(7) The cell bodies showed marked swelling and inequality in form and irregularity in arrangement.

The radiosensitivity of plant tissue was found to differ markedly. Generally, it may be considered that the more immature the cells, the more vivid the reproduction, and the more persistent the mitosis, the greater becomes the radiosensitivity, as was demonstrated by Bergonie and Tribondeau. The author concludes that the irregular arrangement of plant cells and the formation of deformity result after strong irradiation because of the difference in radiosensitivity of the individual cells.

J N ANE, M D

tion Gundo Boehm Ztschr Biol, 1931, XCI, 203-214

The physiologic swelling of resting muscle is due to the over-infiltration of water between the micelle. Isotonic contraction leads to their deformation, which results in interference points in the roentgenograph.

CHEMICAL ABSTRACTS

Investigation of the Histologic Change in Plant Shoots Caused by X-rays Especially the Effect upon the Arrangement of Tissues in the Seed of *Vicia Faba* K Narimatsu Japanese Jour Obstet and Gynecol, February, 1931, XIV, 50-57

Using the seeds of *Vicia faba*, the author studied the effects of the X-ray upon cell arrangement. The dry seeds were soaked in water for from 24 to 48 days before irradiation, then sowed upon a moist saw-dust bed and allowed to send out the principal roots. Those which had sprouted were then placed upon a level glass dish, which was covered with white paper to prevent the seeds from being dried and killed. The dish was then so placed under the X-ray tube that irradiation was evenly distributed. The factors employed were as follows: 140-150 K V P, 2 ma, distance 17-20 cm, duration, 15-60 minutes, no filter, shortest wave length, estimated by the Mark IV spectrometer of Marsch, Stauning, and Fritz, 0.084 Å E - 0.092 Å E.

The irradiated seeds were sown upon a moist saw-dust bed and from three to nine days later were fixed by Flemming's method, Boan's liquid, or formalin solution. Then a series of paraffin specimens were made and stained with hematoxylin eosin, lithium carmine, and by Flemming's solution.

Examination of the sections of the seeds which had received weak irradiation showed no marked abnormality in the cell arrangement as compared with the non-irradiated group. The most marked changes were produced in the nuclei of the cells. Mitosis decreased, the boundaries of the nucleus became indistinct, and the shape of the nucleus changed. In some cases the nucleus was so completely atrophied that the cell-body appeared as if it consisted of protoplasm devoid of a nucleus.

In the group which had received medium irradiation the degenerative changes in the nuclei and swelling of the cell bodies were more marked. In the strongly irradiated group the swelling of the cell bodies was marked, those lying together appearing as if sutured, and the arrangement of the cells presented evidence of abnormality.

The degree of disturbance observed by the author in these experiments was not proportional to the amount of irradiation. This is explained by variations in sensitivity of the individual cells constituting the tissues in the seeds. In this experiment it was also observed that the deeper layer of cells was more markedly affected than the outer layer. Comparative Investigations on the Effect of Bucky and Roentgen Rays on Cell Division G Politzer and J Zakovsky Strahlentherapie, Sept 12, 1931, XLII, 165-170

Salamander larvae, about fourteen days old, were placed in small glass dishes on moist filter paper. Then the larvae were exposed to Grenz rays at 10 cm distance. Every three minutes they were rinsed in cold water in order to prevent changes due to increased temperature. The tube was operated at 10 KV and 10 ma, the duration of exposure varying between five and twenty minutes. The output of the tube was 150 r per minute. Histologic studies of the irradiated larvae

showed that Grenz rays produce exactly the same injuries on cell division as ordinary roentgen rays. It is concluded, therefore, that any difference in the therapeutic effect of Grenz rays cannot be due to any specific action but must be explained on the basis of the absorption law.

ERNST A. POHLE, M.D., Ph.D.

Investigations on the Bactericidal Action of Tissues of Healthy Animals and Those Radiated with X-rays G. M. Antonioli
Strahlentherapie, 1931, LXI, 496-509

The author concludes the following. A weak irradiation of guinea pigs with X-rays increases the bactericidal action of tissues and organs. An intensive irradiation of guinea pigs by strong and frequent doses of X-rays causes a considerable decrease in the germicidal power as compared to the control animals. These biologic changes of the action of X-rays are limited to the reticulo-endothelial cells. The difference of the germicidal action of various tissues and organs of radiated and non-radiated animals can only be explained by the uneven distribution of the reticulo-endothelial system in the animal tissues and organs. The author's experiments prove that small doses of X-rays influence the germicidal action of the reticulo-endothelial system favorably. Large doses, however, react most unfavorably.

CHEMICAL ABSTRACTS

Measurement of the Amount of Mesothorium and Radiothorium in Encapsulated Preparations of Radium Rolf M. Sievert and Ernst Olsson. Acta Radiologica, 1931, XII, No. 66, 15, IV, 121-134

Because the use of very large quantities of radium salts is becoming more and more common in medical practice, it is important to develop a method of measuring the amount of mesothorium and radiothorium in these preparations of radium. The authors of this paper have worked out such a method, based on principles earlier described by Bothe and by Hahn. It is based on the variation in the ab-

sorption of the gamma-rays from Radium C, Mesothorium II, and Thorium C by lead filters of different thickness. It can be used without opening the radium container.

The authors describe in detail their experimental work and the various preparations of radio-active substances measured and used as standards. Tabulations and graphs showing the absorption coefficients of the several radio-active substances studied are incorporated in the paper.

These methods may be used in (1) The determination of the mesothorium content of freshly made preparations containing both radium and mesothorium, (2) the determination of the amounts of radiothorium and mesothorium in such preparations (provided that the quantity of radium present is known) and of the approximate age of these preparations, and (3) the determination of the radium content when the proportion of the radiothorium to the mesothorium is known, e.g., from the age of the preparation. The accuracy of these measurements is greatly influenced by the age of the preparations, but the method is nevertheless usually reliable for detecting any considerable amounts of mesothorium and radiothorium.

A. L. HART, M.D.

THE EYE (DIAGNOSIS)

The Effect of Roentgen Irradiation of the Sympathetic Nerve upon the Eye Hans Salinger and Rudolf Thiel. Strahlentherapie, Sept. 12, 1931, XLII, 96-112

In order to study the response of the sympathetic nervous system to roentgen rays, the authors exposed the ganglion cervicale supremum and the centrum ciliospinale in patients with and without increased intra-ocular pressure. The technic for the irradiation of the ganglion cervicale supremum was as follows. The central ray was directed perpendicular over the center between the angle of the jaw and lower margin of the auditory canal. One-third H.E.D. was applied on the skin (170 KV, 4 ma, 0.5 mm Cu, 30 cm F.S.D.). The exposures were given at eight-day intervals not more than three times. The

intra-ocular pressure was determined with the patient prone on the treatment table before irradiation and immediately afterwards—later at certain intervals. The tonometer of Schiotz was used. The exophthalmos was measured by means of the exophthalmometer of Hertel, while widths of the pupil and the interspace between the lids were determined by the keratometer of Wessely.

In patients with glaucoma the pressure curves of both eyes showed a very characteristic appearance following unilateral irradiation of the ganglion cervicale supremum and the centrum ciliospinale. Following a preliminary increase, there was a definite drop in the pressure lasting several days and being followed by a gradual increase. The curves in both eyes run parallel, i.e., the pressure of the eye on the non-irradiated side changes identically with that of the eye on the irradiated side. In persons with normal eyes the fluctuations were very small. Protrusion of the eye bulb, dilatation of the pupils, and increase of the interspace between the lids were observed and considered as symptoms of sympathetic stimulation. The authors believe that their observations can be considered as proof of the effect of roentgen rays on the vegetative nervous system.

ERNST A POHLE, M D, PhD

Radiography of the Optic Canals R Cassou Bull et Mém de la Soc de Radiol Méd de France, May, 1931, XIX, 225-229

The author has developed a technic for easily and repeatedly demonstrating the optic canals. He finds that the average inclination of the optic canals lateralward from the sagittal plane of the head is from 30 to 35° and the caudal inclination is 15° through a horizontal plane passing through the glabella of the forehead.

The optic canals are situated intracranially at the summit of the orbital pyramid, they must be oriented and radiographed separately. The central ray must be projected in the central axis of the optic foramina.

The patient is placed prone on a table, the glabella and nose in contact with the film, the tube is inclined lateralward 30° and caudal-

ward 15° from the midpoint of the glabella. An exposure is made, the film changed, the tube is then shifted to the opposite side of the head and an exposure made of the opposite optic canal. The author suggests a focus-film distance of 60 cm, and a small cone of X-rays

CHARLES S CAPP, M D

**GASTRO-INTESTINAL TRACT
(DIAGNOSIS)**

Observations of Clinical, Anatomic and Radiologic Natures in a Case of Chronic Ileocecal Invagination of the Colon S Famulari Minerva Med, Nov 3, 1930, XXI, 643-649

This article is essentially a description of a case of ileoceco-colic invagination. The author draws from this study the following conclusions:

(1) The clinical signs of invagination are not always present at the beginning of the process.

(2) Its symptomatology may be very similar to that of other intestinal diseases.

(3) Its duration may be protracted over a long period of time during which signs of an apparent cure may arise.

(4) A neglected chronic invagination always results fatally.

(5) It is possible to reconstruct chronologically the different stages in evolution of an invagination only through accurate studies of clinical, anatomic, and radiologic nature.

L MARINELLI

Fixation of the Iliac Colon by Acquired Bands Radiological Demonstration Alfred C Jordon British Jour Radiol, August, 1931, IV, 387-390

The author believes it possible, by barium enema study, to demonstrate the rather frequent occurrence of acquired bands about the iliac colon. These he considers are the result of constipation. As bands form, the mobility of this part of the colon is restricted, stasis,

inflammation, and narrowing occur, and the results are stasis and dilatation in the proximal colon. The author states also that the abnormal fixation of the iliac colon is a primary factor in the causation of gastric and duodenal ulcer, also that the colon stasis is a factor in the causation of carcinoma of the bowel.

Evidence of band formation consists in showing a delayed filling of the iliac colon, with over-distention of the rectum and pelvic colon. The meal finally trickles through the fixed iliac colon and into the descending colon, the latter part showing dilatation with the iliac colon narrowed. The enema can is then lowered and delay in emptying of the barium from the bowel above the pelvic colon is seen. Apparently, therefore, the diagnosis of bands and kinks rests more on the demonstration of stasis than on lessened mobility.

J E HABBE, M D

Heterotaxia and Incomplete Transposition of Viscera Isaac Natín Semana Méd, June 19, 1930, XXXVII, 1560-1570

Two cases, one of heterotaxia and one of incomplete transposition, were attended by the author, the first one seeking treatment because of pulmonary tuberculosis and the second one because of typhoid fever. The first case had a total transposition as proven both radiologically and at autopsy. In the second case, transposition of the heart, spleen, liver, and stomach was found. The colon, as seen radiologically, did not present any transposition but showed slight deviation from the normal. Neither case had any symptoms referable to its malady. The anomalies of these two cases were found accidentally, and the author presents them because they comprise rare conditions.

N G GONZALEZ, M D

Marked Gastro-intestinal Hyperthyroidism Report of Thirty-four Cases J Russell Verbrugge, Jr Jour Am Med Assn, Aug 22, 1931, XCIVII, 513-517

The thyroid can play an important part in the production of gastro-intestinal symptoms

without giving the usual thyroid syndrome and without demonstrable enlargement of the gland.

Thirty-four cases recognized in a period of three years are analyzed, and four individual case reports are reviewed.

Phenobarbital and compound solution of iodine, as medication, with advice as to rest, diet, mental attitude, and other therapeutic measures, were sufficient in the majority of patients. Nine of eleven treated by radiation were either greatly improved or apparently cured.

C G SUTHERLAND, M B (TOR.)

X-ray Findings in the Gastro-intestinal Tract Julius Gorinskell Med Bull Veterans' Administration, September, 1931, VII, 845, 846

The author discusses briefly the X-ray examinations of the gastro-intestinal tracts of ex-service men and the pathologic conditions most frequently observed in this group of patients.

With the exception of one case of esophageal stricture, no pathologic condition was encountered in the esophagus. Duodenal ulcer was the most frequent finding in the stomach and duodenum. Gastric ulcer and gastro-enterostomy were also quite common. One case of the author's series showed evidences of both ulcer and newgrowth formation. A frequent finding in the colon, which was observed in from 80 to 90 per cent of cases, was a spastic colon, usually seen in the transverse and descending segments.

J N ANÉ, M D

GENITO-URINARY TRACT (DIAGNOSIS)

Calculus Obstruction of the Ureter—Observations Based on an Experience of 120 Cases W Calhoun Stirling Urol and Cutan Rev, September, 1931, XXXV, 547-551

The author divides calculus obstruction of the ureter into the following classes. Those in which impaction is partial, and those cases

in which the ureter becomes completely blocked While complete obstruction may or may not result in dilatation and infection of the kidney pelvis, intermittent obstruction with its resultant renal back pressure frequently produces complete destruction of the kidney

The four most commonly accepted causes of the formation of kidney calculi are as follows (1) Bacteria, (2) colloidal imbalance, (3) vitamin deficiency, (4) urinary stasis The salts of uric acid and urates have been found to constitute about 75 per cent of the stones removed Calcium oxylate and the phosphates occur in smaller proportions The opacity of a stone depends on its atomic weight The 5 to 10 per cent error in ureterography is made up by the uric acid, cystin, and similar stones which cast no shadow Occasionally a stone will be superimposed on the bony pelvis and be overlooked

Approximately 75 per cent of calculi become impacted in the lower ureteral segment, 15 per cent in the upper ureter, and the remainder in the iliac portion In the author's series stones were found in both ureters in 8 per cent and recurrences resulted in 5 per cent

Pain was the outstanding symptom in 89 per cent of cases in this series Nausea and vomiting were present in 29 cases and were reflex in origin Hematuria occurred in 53 cases of the author's group The preliminary routine roentgenogram frequently showed many small opaque shadows near the ureteral orifice which usually represented calcified glands In cases presenting symptoms it is advisable to pass an opaque catheter to positively identify these small shadows, and if further confirmation is desired a ureterogram may be done

The treatment of ureteral stone depends upon the following factors The size, shape, number, and location of the stones, amount of renal infection, the function, duration of impaction, tolerance to cystoscopic manipulation, the age and general condition of the patient, amount of pain, and the degree of fever The author believes that wherever possible conservative treatment should be tried first

J N ANÉ, MD

Strictures of the Ureter W Mulvehill
Am Jour Surg, August, 1931, XIII, 256-262

The author believes stricture of the ureter to be present more frequently than some writers claim He is of the opinion that there are various stages in the pathology of stricture which may render it difficult to diagnose

The end-results of ureteral stricture may be (1) Essential hematuria, (2) hydronephrosis, (3) pyonephrosis, (4) pyelitis, (5) urinary calculi, (6) some medical nephritides, and (7) much of the pathology in congenitally malformed kidneys and many so-called bladder neuroses The etiology is due to the common pyogenic organism No case of gonococcus infection as the cause was demonstrated in this study

Hunner does not believe inflammation of the tubes and ovaries plays a part in ureteral stricture Scott Pugh states that while seminal vesiculitis may be a cause of ureteral obstruction it is never the factor in the formation of ureteral stricture

The author contends that most cases, not considering trauma, are due to hematogenous infection from distant parts of the body

The symptoms are chiefly dull aching, vague pain, backache, and frequency Bladder symptoms are entirely absent in 30 per cent of the cases

In the author's hands, the "hang" of the ureteral catheter has not met with much success in making a diagnosis, nor does obstruction to the introduction of a catheter mean stricture of the ureter

The most reliable method employed is pyelography Intravenous urography has met with the writer's favor in diagnosing ureteral stricture He believes that the dilatation below a stricture in the ureter may be due either to the improper filling with opaque solution at the time of pyelography or to the impairment of nerve supply of the ureter caused by the scar tissues of the stricture, and resulting in atony of the ureter

The treatment of ureteral stricture consists of dilatation He advocates the continuation of this procedure as long as the pain recurs and is relieved by dilatation Approximately

50 per cent of the author's patients were cured, and great relief, for some time at least, was reported in a far greater percentage

In the discussion which followed, Ferrier believed the author to be a little too enthusiastic in regard to the diagnosis of strictures of the ureter. He states that spasm and kinking very often simulate a stricture so that it is frequently necessary, in order to be absolutely certain that one is dealing with a stricture, to take one or two successive roentgenograms to prove that it is consistent and uniform in type, size, and shape.

DAVIS H PARDOLL, M D

Contribution to the Roentgen Diagnosis of Internal Biliary Fistula Gosta Gräberger *Acta Radiologica*, 1931, XII, No 66, 15, IV, 164-174

The author reviews the cases of spontaneous biliary fistulae reported in the literature. He states that fistulae between the bile passages and other organs have been recognized for more than a century and that they have been reported as connecting the biliary tract with the stomach, duodenum, colon, appendix, pleura, pericardium, urinary passages, and uterus. Until the last fifteen or sixteen years, diagnosis was usually made at autopsy.

This condition is not common. Roth, Schroeder, and Schloth reported only 43 cases of internal biliary fistula in 10,866 autopsies. Of these, 19 were between the gall bladder and duodenum and 16 were between the gall bladder and colon. The same relative frequency was found by Courvoisier and Naunyn and by Judd and Burden.

The commonest cause of internal biliary fistula is gallstones. Less frequent causes are (1) Gastric or duodenal ulcer, (2) carcinoma of the stomach, (3) carcinoma of the gall bladder, (4) cholecystoduodenostomy, cholecystenterostomy, or cholecystogastrostomy, and (5) chronic cholecystitis. Most of these fistulae, however, are late complications of cholelithiasis.

X-ray diagnosis of these fistulae depends on the presence of gas or barium, or both, in the biliary tract. It is possible, however, for ba-

rium to pass through the papilla of Vater into the bile ducts when a fistula does not exist. Filling of the ducts with barium in this way has been reported in eight or nine cases of chronic pancreatitis and in obstruction of the jejunum by pressure of a large gastric carcinoma.

The author describes a case of chronic gall-bladder disease in a woman 70 years old. At X-ray examination a fleck of barium was observed outside the duodenal cap in the gall-bladder region, as the barium distended the cap, the fleck became larger. After a few minutes the cap was seen to expel most of its contents back into the duodenum. Cholecystography, done a few days later, showed, instead of dye in the gall bladder, a collection of gas.

The article is illustrated by several excellent reproductions of films in which either barium or gas is seen in the gall bladder or biliary ducts.

In the ensuing number of *Acta Radiologica*, the author has a note on another case which showed gas and barium, apparently in the gall bladder. Cholecystography showed no visible gall-bladder shadow. When the stomach was examined, fluoroscopy showed barium and gas passing into the gall-bladder area. After three hours, when the stomach was empty, barium was still visible in the gall-bladder region, after 24 hours the gall bladder was empty. At operation a diverticulum from the lateral wall of the duodenum was found in the angle between the common duct and the duodenum.

A L HART, M D

GENITO-URINARY TRACT (THERAPY)

Intravenous Urography Hermon C Bampus, Jr. *The Journal-Lancet*, Jan. 1, 1931, LI, 10-13

It is doubtful if, however much the patient might so desire, urography after intravenous injection can replace cystoscopic examination except in individual cases. The amount of

infection in each kidney, determination of separate renal function, and condition of the vesical mucosa, are frequently indispensable. The greatest field of usefulness for intravenous urography is that in which the presence of a second kidney is in doubt, because only one ureter can be found by cystoscopic examination, or injection of one ureter is prevented by stone or stricture.

The determination of functional excretion of the dye is, at present, uncertain. Good visualization occurs not only as the result of good function but is also secondary to renal retention, on the contrary, many normal cases give very imperfect visualization. The causes of these confusing observations have not been fully determined.

W W WATKINS, M D

Use of Intravenous Uroselectan in Trauma of the Urinary Tract Report of a Case of Ruptured Kidney Ben Earle Fillis Urol and Cutan Rev, September, 1931, XXXV, 567, 568

The author reports a case of ruptured kidney in which uroselectan was found valuable in diagnosis and in eliminating peritoneal rupture of the urinary bladder.

The patient, 16 years of age, in moderate shock with symptoms of chilliness, hematuria, nausea, vomiting, and severe pain in left renal and bladder areas, was admitted to the hospital. The history was that of trauma resulting from a hard tackle during a football game four hours previous to admission. Examination at the hospital revealed the following: temperature, 98.4 degrees, pulse, 90, respiration, 20, tenderness of the left upper and lower quadrants of the abdomen, with moderate rigidity of the lumbar and abdominal muscles in this region. Urinalysis revealed bloody urine, with albumin, and red and white blood cells. Blood examination showed a leukocytosis.

The patient was treated for shock and then administered uroselectan intravenously. The resulting uograms revealed a normal right kidney pelvis and vague left renal pelvis. The cystogram was normal and cystoscopy was

negative, except for the ejection of bloody urine from the left ureteral orifice. Indigo carmine, injected intravenously, appeared at the right ureteral orifice six minutes after injection. A diagnosis of complete rupture of the left kidney, with extra-renal and intrapelvic hemorrhage was then made and the patient was given expectant treatment, with frequent blood and urine examinations serving as guides. The subsequent course was uneventful, and the patient, without pain but not entirely free from hematuria, left the hospital on the fourteenth day.

J N ANE, M D

Intravenous Pyelography Carlos Heuser Semana Méd, June 19, 1930, XXXVII, 1605-1608

The author introduces in this article a device which he used for injections for intravenous pyelography. By means of this device, he draws some blood into a bottle and then the fluid to be injected is mixed with it and injected into the patient. The purpose of this is to prevent the formation of scars which occur as a result of extravasation of uroselectan and pyelognost. By avoiding such accidents, the only discomforts that patients may suffer are headache, pain in the shoulder, burning in the throat, and other minor sensations. He presents a case of a patient complaining of pain in the right kidney region, hematuria, and incontinence of urine. Intravenous pyelography was performed and only the left kidney and ureter were found outlined. By serial radiographs, it was found that the left kidney drained well, while the right one did not drain at all.

GYNECOLOGY AND OBSTETRICS

Casuistics of Cured Sarcoma of the Uterus A Herzog Strahlentherapie, Sept 12, 1931, XLII, 198-200

A woman 51 years old was examined in February, 1926. She had had two preg-

nancies and two miscarriages, the last pregnancy had been ten years previous to the examination Menstruation was regular until she was 48 years old From then on the periods were irregular and decreased She was curetted in January, 1925, the histologic diagnosis was cystic endometritis The bleeding stopped after that Beginning in January, 1926, the patient had bleed continuously She complained of hot flashes and pain in the lumbar region The uterus seemed slightly enlarged, but, because of an enormous amount of fat in the abdominal walls, could not be definitely outlined She was curetted and the histologic diagnosis of a polymorphocellular sarcoma made She refused operation and received X-ray therapy in February and May, 1926, and in March, 1927 At that time the uterus was as large as two fists and the left parametrium was definitely involved

Patient did not return until January, 1928, when she started bleeding again She desired operation, which was refused because of the inoperable condition The uterus was larger than on last examination and both parametria were now involved X-ray therapy was given in January, 1928 In March, 1928, the uterus as well as the adnexa appeared normal In October, 1928, she received additional X-ray therapy However, the patient started to bleed again and the uterus began to enlarge Under spinal anesthesia, the radical removal was carried out in November, 1928 Histologic examination verified the diagnosis made in 1926 The patient recovered well from the operation and four weeks later resumed her occupation as midwife She was last seen in July, 1931, still well and without recurrence

ERNST A POHLE, M D , Ph D

Studies on the Mineral Metabolism during Pregnancy and Lactation, and its Bearing on the Disposition to Rickets and Dental Caries Kirsten U Toverud and Guttorm Toverud *Acto Pediatrica*, 1931, XII, Supp II, 1-116

In order to study the predisposing factors to rickets and dental caries, 69 salt metabolism experiments were performed on 30 expectant mothers

The total calcium, phosphorus, and magnesium intake was determined for periods of four days during the last three months of pregnancy The effects of diet and cod liver oil on the inorganic elements in the blood as well as in the breast milk were studied

Dog experiments were also carried out in which the maternal metabolism as well as that of the young was determined

The authors conclude that a negative calcium and phosphorus balance in women is often demonstrated during the latter part of pregnancy, and also, less frequently, during lactation The cause of this negative balance is chiefly deficient mineral content in the everyday diet Vitamin D deficiency may also play a rôle The mineral and vitamin deficiencies in the diet during pregnancy and lactation predisposed offspring to rickets and dental caries The prevention of these diseases ought to be started in fetal life

An extensive bibliography is appended The article is published in English

E C VOGT, M D

X-ray Pelvimetry Dharendra Nath Banerjee and Gonesh Chandra Mukherjee *Antiseptic*, July, 1931, XXVIII, 518-522

Until recently, radiology played a very small part in diagnostic gynecology, the diagnostic use of the X-ray being limited in obstetrics to the determination of the presence or absence of the fetal skeleton A few roentgenologists, however, as early as 1900, attempted to estimate the diameters of the pelvis The various techniques which have been employed for this purpose are reviewed and discussed

The authors' method consists of a combination of the various procedures which have been suggested The method of Thoms is employed by placing the symphysis pubis and the spine of the fourth lumbar vertebra in the same plane, as measured by the pelvimeter from the surface of the Potter-Bucky diaphragm The tube is then centered on the intersection of the line joining the anterior superior iliac spines and midline of the body To

eliminate the necessity of mathematical corrections, because of magnification, a flat brass rod, perforated at intervals of one centimeter, with smaller holes at five millimeters, is employed. This is placed over the thighs at the level of the symphysis in the anteroposterior position and along the spine at the level of the spinous processes of the lumbar vertebrae in the lateral position. In the lateral roentgenogram the promontory of the sacrum is distinctly seen, but the symphysis pubis is often difficult to localize. The authors claim fairly accurate measurements of the pelvis, employing this method.

J N ANE, MD

Radiation in Pelvic Disease John F Herrick. Jour Iowa St Med Soc, February, 1931, XXI, 63-66

The author concludes a general discussion with this summary. The first requisite is a correct diagnosis; radiation treatment must be carefully controlled and measured by one well qualified. Cases must be carefully selected. Usually radiation is contra-indicated in acute inflammatory disease of the pelvis. Ovarian tumors are not usually suitable for radiation, except in malignant disease, when radiation before and after removal is indicated. Radiation is the treatment of choice in uncomplicated fibroids in women between 38 and 50 years of age. Cancer of the cervix is best treated by radiation, both in cure and prevention. Cancer of the body will yield to radium as certainly as to surgery.

W W WATKINS, MD

HEART AND VASCULAR SYSTEM (DIAGNOSIS)

Concerning the Universal Thoracic Pulsation Manuel del Sel and Alberto C Taquini Prensa Méd Argentina, July 30, 1931, XVIII, 255-259

The author presents a case of posterior aneurysm of the transverse and descending arch of the aorta. The clinical diagnosis was

based mainly on the thoracic pulsation, which the author attributes to an advanced aneurysm with destruction of the thoracic wall, causing a movement of expansion. The diagnosis was confirmed with fluoroscopy and radiograms. He concludes that such a posterior aneurysm can be diagnosed clinically through this pulsation, instead of relying entirely on X-rays, as has been the custom.

N G GONZALEZ, MD

Clinical and Radiologic Contributions to the Study of the Azygos Vein Lorenzo Crosetti. Minerva Med, Apr 21, 1931, XXII, 606-614

In reviewing the embryologic theories pertaining to the origin of the azygos vein and the literature existing on the subject, the author points out that both statistics and interpretation of radiographs are somewhat contradictory. He describes and criticizes in detail the various technics used and enumerates those which are most likely to yield satisfactory results. This article includes five complete reports suitably illustrated which, incidentally, were the only ones occurring in 514 observations made at the author's clinic for the study of tuberculosis. Teleradiography was used, with exposures of one-tenth of one second.

The author believes that the difficulty encountered in the interpretation of a film is due either to the lightness of the opaque band of the meso-azygos or to its unusual location, and that it is very easy to mistake the image of the vein for shadows of old sclerotic lesions or calcified nuclei. The anomaly may cause an hypophonia of different intensities in the corresponding apical field. This sign should be of further aid to the semeiotic control, but it must be confirmed by appropriate radiologic examination.

L MARINELLI

HODGKIN'S DISEASE (THERAPY)

Four Cases of Hodgkin's Disease Treated with Radium H E Guerrero New Or-

leans Med and Surg Jour, April, 1931, LXXXIII, 698-705

In the cases reported, only the cervical glands were involved, the swollen glands being treated with radium in conjunction with which Fowler's solution was given. The masses uniformly decreased in size and pain disappeared. Such lesions are very difficult to differentiate from tuberculous adenitis, lymphosarcoma, and leukemia in its aleukemic stages.

W W WATKINS, M D

The Disappearance of Tuberculin Energy in Patients Afflicted by Malignant Lymphogranuloma who have Undergone X-ray Treatment Cesare Rotta Minerva Med, April 21, 1931, XXII, 601-606

The author presents the complete clinical reports of five patients suffering from Hodgkin's disease, whose reaction to 1 per cent solution of Meister-Lucius tuberculin was negative before X-ray treatment and positive afterwards. He also mentions two similar cases which occurred to Professor Micheli. The tests were performed immediately before the cycle of treatments, and a month after the end of it. The doses of radiation given were very large in all cases and varied from a minimum of 2,000 r to a maximum of 6,000 r.

The author advances the hypothesis that roentgen treatment has brought the patients to the relatively normal state of positive reaction found in most individuals.

L MARINELLI

THE KIDNEY

Acquired Renal Dystopia or Movable Kidney Frank Kidd Jour Urology, September, 1931, XXVI, 327-378

The types of renal dystopia are reviewed and a fresh hypothesis is formulated which attributes the most important pathologic type to the persistence from neolithic times of a racial stock of Egyptian origin and descent. The importance of the intra-abdominal pressure is minimized, and the significance of the suspensory ligaments of the kidneys are emphasized. The pathology of movable kidney

is placed on a fresh plane, being brought into line with the pathology of sprains and deformities. Pyelography is advocated as the only real guide to treatment, and as the indicator of the reasons for success or failure of operations. An operation for renal dystopia is described, and the points essential for success in operating outlined.

Brandsford Lewis' discussion of the author's paper dwelt in particular on the evidence of stasis in the pelvis and the emptying time of this organ. He also stressed the differential diagnosis.

Clyde Leroy Deming claimed that it is within the realm of every trained urologist to determine conclusively by cystoscopic and roentgenologic examinations, whether or not the nephroptotic kidney is the organ which is responsible for the clinical manifestations. The severity of the component manifestations, the functional disability of the kidney and its influence upon the adjacent organs determine the indications for surgical treatment.

Under indications, the following factors are to be considered:

- (1) Pain,
- (2) pelvic and ureteral stasis,
- (3) chronic pyogenic infections of the kidney,
- (4) ureteral kinks,
- (5) rotations and torsions,
- (6) traction on adjacent organs,
- (7) general visceroptosis,
- (8) aberrant vessels,
- (9) calculus,
- (10) neurasthenia, and
- (11) failure of palliative treatment.

The contra-indications for surgical treatment were stated as follows:

- (1) Movable kidney which does not give pain or shows no infection and has normal function and normal emptying time,
- (2) voluminous hydronephrosis,
- (3) enlarged liver and spleen,
- (4) stenosis of uretero-pelvic outlet,
- (5) large calculus with pyonephrosis,
- (6) tuberculous kidneys, and
- (7) non-surgical risks.

Deming described his operation for nephroptosis and his results.

William F Braasch said that the indications for operation are logical and sound. If they are followed, many operations for nephroptosis which are now being done, will be avoided. On the other hand, that there are indications for operation in a small number of carefully

selected cases is proved by the post-operative results which the author has secured and has demonstrated by means of urography

Oswald S Lowsley stated that the endocrine relationship to nephroptosis should be considered. Thorough mobilization of the kidney and ureter is essential for successful nephropexy. He stressed the importance of urography as a factor in the diagnosis. Palliative measures for one year are advocated. Every ptosed kidney should not be operated, general visceroptosis should be borne in mind. It is poor judgment to fix a badly damaged kidney which should be removed. It is equally inadvisable to operate on a ptosed kidney which is draining properly and is symptomless.

Thomas D Moore stressed the importance of serial pyelographic films during expiration and inspiration, in order to determine the degree of renal excursion, kinks, fixation, and other important data.

The author closed his paper by stating that one must pick his cases in order to get the wonderful results claimed for nephropexy. Palliative treatment should be tried first by all means.

At operation the kidney is anchored, not fixed. Very soon the adhesions made at operation once more begin to stretch and the kidney again takes on in a few weeks a definite and swinging action. This action is never as great as before operation and thereby the kidney retains its high position.

DAVIS H PARDOLL, M.D.

Influence of High Protein Diets on the Kidney R Klein and O Bergeim Proc Soc Exper Biol and Med, 1931, XXVIII, 590, 591

Various types of protein in a standard diet were fed to 36 rats in groups of 9. One rat in each group was killed by CHCl_3 after 19, 35, 70, and 135 days, the kidneys were weighed and examined histologically. Rats fed a diet of 75 per cent protein showed renal hypertrophy in 40 per cent of the cases. Rats receiving meat powder or keratin along with

60 per cent casein in their diets for from 35 to 135 days showed swelling of the tubular cells, degeneration of the nuclei, and many tubular casts. The changes were most marked in the group receiving meat powder. The indigestible protein of horn with its presumably accompanying intestinal putrefaction had no marked effect upon the kidneys. Predigestion of the casein, which should facilitate the absorption of amino acids, did not seem to influence the result.

CHEMICAL ABSTRACTS

MEDICAL PRACTICE

The Problems of Radiology in India P B Mukerji Antiseptic, July, 1931, XXVIII, 464-472

With the firm conviction that the practice of radiology should be recognized as a specialty in the practice of medicine and that the radiologist should be considered as a consultant and a specialist, the author discusses and suggests solutions of the many problems confronting radiologists in general and those of India in particular. The proper education of the medical profession and the public in this regard is believed of utmost importance.

The qualifications of a radiologist as summarized by Martin are as follows: (1) Possession of a degree in medicine from a recognized university, (2) a command of the best technical procedures used in diagnostic radiology, (3) a thorough knowledge and experience in roentgenographic interpretation, (4) a knowledge of modern medicine sufficiently broad to make him a true consultant, (5) a broad knowledge of radiotherapy with reasonable experience in this field, (6) the ability and willingness to teach, (7) some familiarity with research problems. The term "radiologist" should not be confused with "radiographer." A radiographer is a lay-assistant, a non-medical man, or a technician who knows how to handle X-ray equipment in order to obtain roentgenograms, or to carry on X-ray therapy when the dosage has been prescribed by a radiologist or a physician trained in the science of radiology. While

the technical work can be performed efficiently by a radiographer, the interpretation of roentgenograms and fluoroscopy in terms of pathology should be done only by a radiologist, who has a knowledge of pathology, clinical medicine, and surgery.

The author believes that if the X-ray department of a hospital is to be of real value, a radiologist should be in charge. The practice in many hospitals of adding the radiologic work to the duties of the already overworked medical officer does not lead to the best that can be obtained in the practice of radiology. It is absurd to expect general practitioners, such as medical officers in charge of hospitals, to keep abreast of all advancements and developments in a specialty of medicine, which is the most technical of medical specialties. The proper solution, in the author's opinion, is the placing of a radiologist in charge of the radiologic department.

The importance of roentgenology has often been improperly interpreted by the public and what is much worse, also by some doctors who believe or make their patients believe that with the aid of roentgenology all occult diseases may be diagnosed. On the other hand many clinicians regard radiology as a joke not worthy of their consideration, or request a roentgenogram made but desire to interpret it themselves, thus treating the radiologist as a photographer. Clinicians should require from radiologists what they expect from other qualified specialists, and the radiologist should be given the essential clinical data and if possible an indication of the clinician's opinion.

In almost all of the universities in India, with medical faculties, attendance at a course of from six to fifteen lectures in radiology is demanded of the students. The author believes that at least twenty lectures are necessary to impart to the students a satisfactory foundation in radiology. He further deplores the fact that there are professors in almost every branch of medicine in Indian universities except in radiology.

J N ANÉ, MD

gards Diagnosis and Therapy M D Joshi
Antiseptic, July, 1931, XXVIII, 449-463

Like all new discoveries and inventions, radiology has passed through the stages of ridicule, opposition, and suspicion, but it is now recognized as one of the most essential and important additions to our armamentarium of diagnosing and treating various pathologic conditions. Radiology does not deprive the practitioner of his acumen in diagnosis, for if properly utilized and interpreted, it serves rather to improve his methods of clinical diagnosis by enabling him to correlate more accurately the clinical data with the pathologic changes. The author considers it the duty of the radiologist to carefully investigate the clinical data before making a radiologic diagnosis.

The author discusses the preparation of the patient and the value of radiology in the diagnosis of diseases of the bones, joints, chest, alimentary and urinary systems, in gynecology, and in obstetrics. He further classifies and discusses therapeutic radiology.

Inflammatory affections of bones are characterized by the fact that there is no sharp demarcation line between the affected and normal portions of bone, and by the presence of periosteal reaction. Radiologic examination is particularly useful in detecting and locating sequestra. Tumors of bone are characterized by the presence of a sharp line of demarcation between the normal and involved bone and by the absence of periosteal reaction.

X-ray examination of the chest will demonstrate the following: (1) Affections of the ribs or thoracic vertebrae, (2) pathologic conditions of the pleura and pleural cavity, (3) consolidation, fibrosis, or cavity formation in the lungs, (4) conditions of the bronchi and hilum glands, (5) size and shape of the heart and aorta, and (6) enlargement of the thymus and mediastinal glands or mediastinal tumor.

In the study of the alimentary tract he recommends the use of barium sulphate in buttermilk as the opaque meal. Various pathologic conditions of the esophagus, stomach, duodenum, cecum, appendix, and colon may thus be studied and differentiated. The gall bladder is best examined after the

oral administration of sodium tetraiodophenolphthalein

X-ray and radium are employed in the therapy of many diseases which are intractable either to medical or surgical treatment. Generally, radium should be used for small localized lesions, whereas it is more convenient to give X-ray exposures on extensive lesions, such as secondary carcinoma. Besides their use for malignancy radium and X-ray therapy are useful in many other conditions, such as leukemias, tuberculous glands, fibroids, keloids, lupus, eczema, psoriasis, and rodent ulcer.

The author concludes that proper co-operation between the clinician, pathologist, and radiologist will make possible a much more rapid advance in radiology.

J N ANE, M D

MYOSITIS OSSIFICANS

Contribution to the Casuistry of Post-traumatic Muscular Ossifications I Bigliardi L'Ateneo Parmense, May-June, 1931, III, 160-168

The study of post-traumatic muscular ossifications, begun by Billroth, in 1872, may now be said to be complete, especially since, with the advent of radiology, we have been enabled to study this rather unusual lesion with detailed and prolonged observations to determine in part its origin, and to follow its clinical evolution.

Of particular interest is the radiographic study of muscular ossification. In the first period, soon after the trauma, there is noted the presence of a circumscribed and rather faint shadow somewhat more opaque than that of the muscular tissue and of much smaller volume than the palpable mass. This shadow, in successive examinations made at increasing periods of time after the trauma, takes on constantly greater opacity, with the formation of darker, intermingled with lighter, zones, since the neoformation is not the result of a single osseous mass, but often of various fragments

made up of connective tissue, muscular fibre, and adipose tissue.

This shadow finally assumes the characteristic skeletal opacity, then slowly retrogrades until there remains on the plate only a small, thin focus of ossification which soon entirely disappears.

The author studied four cases of post-traumatic muscular ossification in the Radiologic Institute of the Ospedale Maggiore, of Parma. The first two were cases of ossification of the brachial muscle. The first is of particular interest, in view of the precocity of the osseous neoformation observed within a period of ten days after the trauma. The third case showed ossification of the great lateral muscle, while the fourth report described a case of Pellegrini-Stieda's disease.

It is certain that at the present stage of science nothing is definitely known regarding the genesis of this species of ossification. The various theories expounded have been in part superseded, while others fail to withstand scientific test. Undoubtedly, that of Orlow satisfies better than any other the clinical tests and experimental results.

NERVOUS SYSTEM (GENERAL)

Experimental Investigation of the Effect of Roentgen Rays upon the Vegetative Nerve Part I—The General Action of X-rays, Especially the Relation with Blood Pressure S Suzuki Japanese Jour Obstet. and Gynecol., June, 1931, XIV, 207-213

Experimenting with healthy female rabbits, the author studied the effects of X-irradiation upon the vegetative nerves as demonstrated by changes in the blood pressure. The factors used were as follows: Effective pressure, 150 KV, 2 ma, focal skin distance, 23 cm, no filtration, time, 35-40 minutes. An abdominal field 8 X 6 cm was selected and the remainder of the animal protected by 3 mm of lead rubber.

The highest blood pressure of the healthy control animals was found to vary from 86 to

108 mm Hg, with a pulse pressure of from 5 to 6 mm Hg. One hour after irradiation the blood pressures, as a whole, showed a very slight fall, but the pulse pressure increased generally and in some cases rose to 22 mm Hg. From two to three hours following irradiation there occurred a marked fall in blood pressure in all of the animals. The blood and pulse pressures returned to normal in from seven to ten days.

Comparisons of the effects upon the blood pressure of adrenalin in control and irradiated animals were also made. One hour after irradiation the rise in blood pressure following adrenalin was only slightly restrained. This antagonistic action to adrenalin was greatest from three to five hours following irradiation and persisted for from seven to ten days, at which time the normal conditions and reactions returned. It was possible also to abolish this restraining effect to the action of adrenalin at any time after irradiation by the administration of atropine.

Similar experiments were performed on healthy non-irradiated animals, using pilocarpine as a stimulant to the parasympathetic nerves, results similar to those noted in the irradiated series being observed in every case. The author, therefore, concludes that X-irradiation produces a hypertonic condition of the parasympathetic nervous system.

J N ANÉ, M D

Experimental Investigation of the Effect of Roentgen Rays upon the Vegetative Nerve Part II—Pharmacologic Investigation of the Effect of Irradiation on the Inferior Mesenteric Ganglion upon the Uterine Motion. S Suzuki Japanese Jour Obstet and Gynecol, June, 1931, XIV, 214-217

The author irradiated the inferior mesenteric ganglions of rabbits and studied the effects upon the uterus. Following laparotomy a lead cylinder was placed over the inferior mesenteric ganglion, and the remaining tissue, including the uterus and ovaries, were protected by a lead-rubber plate. The factors used were as follows: 150 KV, 2 ma, distance, 23 cm, no filtration, time, 35 minutes,

the shortest wave length, 0.78-0.80 Å. The drugs employed were adrenalin, pilocarpine, pituglandol, secacornin, and barium, which were injected into the auricular vein.

The day following irradiation the uterine tissue was found only slightly sensitive to secacornin and barium, but markedly sensitive to pilocarpine. From nine to eleven days following irradiation, marked sensitivity was noted to all the drugs employed. A decrease in sensitivity occurred from 20 to 21 days after irradiation, but from 28 to 30 days following X-radiation uterine excitability again increased, so that sensitivity was greater at this stage than at any other time. Microscopic examination of the irradiated inferior mesenteric ganglion revealed retrogressive changes. The uterine tissue showed evidences of congestion and development of glands of the muscular layer. Thus, the effects noted upon the uterus were secondary to those observed upon the ganglion. The author believes that the increased sensitivity to pilocarpine on the day following irradiation was due to the hypertonic condition of the parasympathetics, induced by the irradiation.

The Biological Effect of High Voltage X-rays Charles Packard and C C Lauritsen *Science*, March 20, 1931, LXXIII, 321, 322

The well known studies of Packard and Wood, on the killing effect of roentgen rays of various wave lengths upon the ovum of *Drosophila*, have been extended to an average wave length of 0.04 Å U, produced by Lauritsen's 550 KV tube in the California Institute of Technology The previous results, namely, that the same number of r-units applied produced the same biologic effect independent of the wave lengths was again confirmed for these hard rays produced with 550 kilovolts The same results were obtained with a mouse tumor (Sarcoma 180) The lethal dose was tested by inoculation of radiated small pieces into healthy animals A

number of tests with the particles radiated at 550 KV showed the lethal dose to be about 2,750 r This agrees well with the dose found by Wood by the same tests at softer rays (0.20 and 0.70 Ångstrom unit)

OTTO GLASSER, Ph D

Several Facts Concerning Cancer Tissue as Brought Out by Radiotherapy Cl Regaud Arch Rad Institute, University of Paris and Curie Foundation, 1931, II, Part 3, 371-383

In a typical epidermoid epithelioma the cancerous tissue evolves between a zone of multiplication (ordinarily peripheral, and where the germinative cells are situated) and a zone of desquamation (ordinarily central and occupied by the squames which terminate the sterile cellular lines) In other cancers, the germinative cells and the cells of the sterile lateral lines are mixed In still others lateral lines are not found, all the cells appear fertile

The histologic study of the transformation of epidermoid cancer tissue treated by radiation demonstrates the following The disappearance of the germinative cells, the continuation of evolution of the cells of the lateral lines towards keratinization, the increase, then the resorption of the masses of squames, and temporary modifications in the population of the connective tissue

A series of analogous phenomena observed in the thymus treated by rays has shown that the corpuscles of Hassall are formations which are not permanent but variable

Everything leads to the conclusion that, in a non-irradiated epidermoid cancer, the clumps of squames (horny pearls) are formations which are not permanent but variable—whose volume at any moment represents a difference between their increase and their resorption

The internal life of cancerous tissues is not only a question of phenomena of increase, but also of phenomena of resorption, the increase in volume of the tumor is a measure of the

difference of intensity of these two phenomena

Holocrine secretion, of which cancerous tissues are the site, could furnish a plausible hypothesis for the explanation of the eventual acquisition of special properties by the serum of those afflicted with cancer

RADIATION SICKNESS

The Symptomatic Treatment of X-ray Sickness Following Roentgen Deep Therapy E B Huffer Strahlentherapie, Sept 12, 1931, XLII, 181-188

The author has treated a series of patients who received X-ray deep therapy with preparations usually prescribed in sea sickness One is called "vasano" and the other "nautisan" The first is a mixture of hyosciamin and scopolamin 3 1, and the second contains chiefly trichlorisobutylalcohols with an addition of caffeine He obtained good results in a high percentage of cases and recommends these drugs, therefore, in the prevention or treatment of X-ray sickness A combination of both did not improve the results

ERNST A POHLE, M D, Ph D

Roentgenotherapy and Cholesterol Content of the Blood Serum Colsil and X-ray Sickness Elisabeth Willms Strahlentherapie, Sept 12, 1931, XLII, 171-180

This study was undertaken to determine the cholesterol changes in the blood serum following irradiation, as well as the therapeutic value of colsil (cholesterol pills) in the prevention or treatment of X-ray sickness

It appeared that patients with malignant tumors usually had an increased cholesterol content in the blood serum, varying between 0.276 mg per cent and 0.484 mg per cent Twelve out of nineteen cases showed the increase in either normal or subnormal values Cholesterol determinations were also made before and after X-ray therapy No correlation could be established between the X-ray

sickness and cholesterol content in the blood serum If normal persons received colsil, the cholesterol content in the blood serum was higher and remained so up to twenty-four hours following the administration Of eight treated cases, four had X-ray sickness in spite of colsil, one patient who had the most violent attack of X-ray sickness had a higher cholesterol content in the blood serum than before irradiation

It is concluded, therefore, that the cholesterol changes in the blood serum are not alone responsible for X-ray sickness Colsil must not be considered of curative value in all cases but may help a certain group of patients

ERNST A POHLE, M D, Ph D

RADIUM

Physics of Radium and Radium Therapy M J S Pillai Antiseptic, July, 1931, XXVIII, 491-498

Radium therapy originated in 1901, as a result of the famous "Becquerel burn" Radium is a metal of the alkaline earths, similar to calcium, barium, and strontium Its atomic weight is 226.45 and its melting point is 700 degrees centigrade Alpha, beta, and gamma radiations are emitted simultaneously, their relative proportions being approximately 10,000 100 1

The alpha-rays of radium are atoms with a positive electric charge and are deflected by strong electric or magnetic fields Alpha-rays are absorbed by about three inches of air, or thin sheets of paper, metal, or rubber Beta-rays are similar to the cathode rays, but are more penetrating The hardest of these rays do not penetrate more than three-eighths of human tissue, 4 mm of aluminum, or 1 mm of lead Gamma-rays are similar to X-rays, although the hardest gamma-rays are more penetrating

The methods of application of radium are as follows Surface application, teleradiotherapy, and interstitial The author advises the careful preparation of the patient before employing radium therapy and suggests the

following precautions (1) All septic foci should be eliminated, (2) a red blood count of below 1,000,000 per cc is a contra-indication to radium application, (3) massive doses of radium should not be employed in the treatment of advanced lesions of the liver, kidneys, or heart, (4) in cases of lesions of the pelvis, situated deeply, a combined treatment of radium and deep X-ray therapy is more valuable than treatment with either alone, (5) the treatment of menorrhagia should be administered soon after the menstrual period ends, in order to avoid the usual reactionary excess which follows treatment, (6) in general, a diagnosis describing the exact pathologic condition of the involved tissue will prove valuable in the proper application of radium therapy

It has been established that some tissues are more easily controlled and destroyed than others. The response to irradiation is further modified by the nature of the resistance of the patient and the size, site, and condition of the tumor. In general, radiosensitivity is found to be greater in cells with greater reproductive capacity.

Very much brilliant work has already been accomplished in the study of radium therapy and its application. The author believes that the close co-operation of physicists, clinicians, radiologists, and pathologists will accomplish very much in adding valuable information to our knowledge of this form of therapy. He cautions against the dangers resulting from the use of radium by unskilled workers.

J N ANE, M D

ably There is no appreciable loss in potency if the activation is carried on to even as much as a 20-fold excess. There are some decomposition products formed in all cases.

The methods of application of radium are as follows Surface application, teleradiotherapy, and interstitial The author advises the careful preparation of the patient before employing radium therapy and suggests the

apy K P Mody Antiseptic, July, 1931, XXVIII, 512-517

While X-rays are somewhat similar to light waves, the wave lengths of the roentgen rays are so much shorter that their effects on human tissues are much more profound and powerful. X-rays are composed of rays of many wave lengths, the long waves having their maximum effect on the skin, and the short ones penetrating deeply. In this manner, the wave lengths are selected according to the nature and depth of the lesion.

A malignant tumor—being a purposeless, irrational, irregular reproduction of cells, serving no useful purpose, replacing, invading, and destroying healthy tissue—naturally does become a rather complicated problem. The cells are in various stages of division and reproduction and vary in their response to the X-rays, for some are radiosensitive and others are radioresistant. The X-ray dosage should be such that all of the pathologic cells are destroyed but the minimum danger done to the normal surrounding tissue.

Many methods are used to determine the X-ray dosage applied. The pastille method of Sabouraud while excellent for superficial therapy is unreliable in deep therapy. The skin tolerance dose method of the Germans is believed by the author to be of some value. However, individual variations in sensitivity to the rays occur which render the accurate estimation of the erythema dose difficult. In spite of inaccuracies, the author is of the opinion that the erythema unit dose method remains as the most practical method of dosage yet evolved. The use of the "sphere gap" and the iontoquantimeter of the French is also mentioned. The design of the latter type of apparatus is based on the fact that air, ordinarily a non-conductor, becomes a good conductor when the X-rays are directed on it. The determination of the "depth dose," which depends on the voltage, filter, and skin-target distance, is of great importance.

There is some difference in opinion regarding the period of time during which the full dose should be given. In some laboratories the total dose is given at a single sitting. The disadvantage of this technic is that it is very exhausting to the patient and in some cases

results in considerable disturbance to the general health. The French, on the other hand, divide the total dose into several sittings. The neoplastic cells are in different stages of division and reproduction and by applying divided doses it is hoped that all the cells may be destroyed during the radiosensitive phase.

Outline of Roentgen Diagnosis (first paper) Leo G Rigler Journal-Lancet, Feb 15, 1931, LI, 143-147

This article is the first of a series on the subject, running in this journal. This paper covers the following points: (A) Nature and Value of Roentgen Examination, (B) X-ray Films—(1) characteristics of a roentgenogram, (2) factors affecting the production of an X-ray film, (3) common errors and confusing shadows, (4) technical facts of especial importance, (C) X-ray shadows in the body—(1) gas, (2) fat, (3) internal organs, (4) muscles, (5) blood-containing organs, heart, blood vessels, (6) calcium, (7) foreign bodies, especially metallic, (D) Aids to Examination—(1) general considerations, (2) introduction of air or other gases, (3) barium and bismuth salts, especially barium sulphate, (4) sodium iodide, etc., (5) iodized oil, (6) gall-bladder dye, (7) uroselectan, (E) Methods of Roentgen-ray Examination and Their Attributes—(1) films, (2) fluoroscopy, (F) Diseases and Organs which should be Examined with the Roentgen Ray as an Aid to Diagnosis—(1) osseous system, (2) the head, (3) respiratory tract, (4) heart and great vessels, and, to a lesser extent, all the arteries, (5) diaphragms, mediastinum, thymus, and thyroid, (6) gastro-intestinal tract, (7) gall bladder, (8) urinary tract, (9) genitalia, (10) pregnancy, (11) miscellaneous conditions, (G) Definition of Terms.

W W WATKINS, M D

Outline of Roentgen Diagnosis (second paper) Leo G Rigler Journal-Lancet, March 1, 1931, LI, 181-184

This paper considers the following: Bones

rats as compared with animals which have rickets, as observed by themselves and by Suhrmann Their results do not agree with those reported by the latter In a brief communication, Suhrmann and Kollath offer several explanations for the discrepancy

ERNST A POILLE, M D, Ph D

ROENTGEN DIAGNOSIS AND THERAPY

The Rôle of Radiography in the Diagnosis of Diseases of the Lung S K Basu Antiseptic, July, 1931, XXVIII, 510, 511

The author considers X-ray examination of the lungs superior to physical examination in the following conditions (1) Early tubercle complicated by bronchitis, (2) deep-seated and closed early lesions, (3) hilum tuberculosis, (4) recrudescence of old lesions, (5) necessity of application of artificial pneumothorax treatment successfully

It is emphasized, however, that in all cases a physical examination should be made and correlated with the roentgenographic findings

J N ANE, M D

Radiology in Diagnosis M Mukherji Antiseptic, July, 1931, XXVIII, 473-490

The author discusses the indications and limitations of radiology in the diagnosis of disease In order that radiology may be a reliable diagnostic aid, it is essential to have a standard of minimum requirements for the roentgenologist and roentgenography The roentgenogram should be so made that the utmost of detail and contrast is obtained Having procured such a roentgenogram it is necessary that it be interpreted in terms of pathology by one who has been properly trained in this work.

The radiologist should possess a working knowledge of applied anatomy, pathology, and physiology, together with a general knowledge of medicine and surgery, besides his specialized knowledge of the science of radiology He should have the co-operation of the clinician and pathologist so that he may have the opportunity for studying and

following up the cases after they have passed through his hands Confirmation of diagnosis creates self-confidence and increases the diagnostic ability of the radiologist In like manner, attendance in the operating room and postmortem room will prove valuable aids in the study of disease The radiologist should not be considered an intruder by the clinician, but these two practitioners of medicine should meet and discuss the data obtained

Radiology has been extremely valuable in giving us a truer knowledge about "practical normals" as met with in the every-day practice of medicine, in contradistinction to the "theoretical normals" of the dissecting room The author suggests the inclusion of such a course of X-ray demonstrations of the normal human anatomy from the living in the curriculum for the students in the various medical schools and colleges Our idea of "habitus" resulted from the X-ray examination of large numbers of healthy persons of different body builds Thus the normal variations in the size, shape, and position of the abdominal and thoracic viscera were noted and consequently fewer cases of ptosis of the colon and stomach have been diagnosed In this manner, radiologists have recognized the normal variations in "practical normal" chests

The author discusses the value of radiology in pathologic conditions of the various organs and systems Next to laparotomy, radiologic examination affords the most accurate information as to the presence or absence of diseases of the stomach or intestines He especially emphasizes the value of fluoroscopy in gastro-intestinal work, for indirect and direct signs can best be studied on the screen In gastro-intestinal work the value of radiography lies not in demonstrating the alterations that cannot be seen on the screen but in corroborating the fluoroscopic observations and giving time to the roentgenologist to come to a well-reasoned conclusion

X-ray Therapy Its Principles and Practice, with Special Reference to Deep Ther-

lesions, right heart hypertrophy and failure, generalized cardiac enlargement, congenital heart disease, pericardial effusion, adhesive pericarditis), and pathologic changes in the aorta

W W WATKINS, M D

Outline of Roentgen Diagnosis (ninth paper) Leo G Rigler Journal-Lancet, Aug 1, 1931, LI, 478, 479

This paper deals with the following. The mediastinum (including normal appearance, mediastinitis, mediastinal effusions, mediastinal abscess, substernal thyroid, dilated large veins of the neck, thymus gland, dilated esophagus, paravertebral abscess, glandular enlargements, tumors) and the diaphragms

W W WATKINS, M D

Outline of Roentgen Diagnosis (tenth paper) Leo G Rigler Journal-Lancet, Sept 1, 1931, LI, 547-550

This paper continues the study of the diaphragms. The pleura is then taken up under the headings of general considerations, pleural thickening, pleural effusion, pneumothorax, hydropneumothorax, tumors. The next division includes the lungs, trachea, bronchi, under the subheads of value of X-ray examination, technical consideration, and methods, normal appearance

W W WATKINS, M D

X-Ray in Diagnosis of Thoracic Pathology Hermon Harrison Cole Illinois Med Jour, September, 1931, LX, 260-262

What should a clinical diagnostician expect of the radiologist in the thoracic field? What has the radiologist a right to expect in return? If both are to make the diagnosis, then the facts of the history, physical findings, and laboratory findings should be in the hands of both men

The radiologist, purely on his own, can interpret light and shadow in terms of relative tissue density and note unusual locations. It

is unfair to him and often dangerous to his reputation to ask him to do more. To refuse a diagnosis by radiography alone takes more courage than shrewd guessing.

Differences between anthracosis, silicosis, bronchopneumonia, carcinoma, fibroid tuberculosis, and syphilis are not clear enough at times for certain X-ray identification. The radiologist has a right to history, blood examination, sputum, and other pathologic reports and physical findings.

The author insists that the radiologist read the plate in terms of pathologic densities without reference to final diagnosis. This last is the province of both working together, or of the clinician alone.

He believes that all chest plates should be made with a minimum of exposure and at two meters distance. Stereoscopic plates should be the rule. We have not learned to use lateral and oblique views as often or as intelligently as we should.

ROENTGEN RAY (INDUSTRIAL APPLICATION)

Radiographic Inspection of Metals Herbert R Isenburger Mech Engineering, October, 1931, LIII, 1-8

Radiographic examination is one of the most reliable methods of non-destructive routine testing of the structure of metals. In this work roentgenograms made by means of a penetrating radiation of X-rays are known as "exographs" as distinguished from "radiographs" made by means of gamma-rays obtained from radium or its emanation.

The author believes that X-rays should be employed on steel castings and forgings having a thickness of three inches and less, and that gamma-rays should be used for examination of heavier material. More detail, better contrast, and a shorter exposure time result from the use of X-rays, therefore this form of radiation should be used whenever possible.

Radiography is of great value in foundry

and Joints (normal characteristics as to growth and normal variations), Traumatic Conditions of Bones and Joints—(1) Fractures, (2) Information gained from X-ray examination in cases of bone injury, (3) Characteristics of various fractures, (4) Non-union, (5) Operative findings, (6) Infected fractures, (7) Periosteal tear and traumatic periostitis, dislocations

W W WATKINS, M D

Outline of Diagnosis (third paper) Leo G Rigler Journal-Lancet, March 15, 1931, LI, 204-208.

This paper covers the following Infectious Processes of Bones, as acute, chronic, and secondary osteomyelitis, acquired syphilis, tuberculous osteomyelitis, and miscellaneous conditions, Bone Tumors, under the headings of general considerations, benign and malignant tumors (primary and secondary), Hodgkin's disease, and Paget's disease. These are correlated with the classification of the American College of Surgeons

W W WATKINS, M D

Outline of Roentgen Diagnosis (fourth paper) Leo G Rigler Journal-Lancet, April 1, 1931, LI, 233-235

This article covers the following Diseases of Joints, under the subdivisions of "Normal appearance," "Points to be noted in the study of joint lesions," "Classification and terminology," "Findings in joint lesions" (including acute rheumatic fever, acute arthritis, chronic arthritis resulting from the foregoing, chronic arthritis of non-specific etiology, gout, osteochondritis dessicans, osteochondromatosis, Charcot joint, tuberculosis of joints)

W W WATKINS, M D

Outline of Roentgen Diagnosis (fifth paper) Leo G Rigler Journal-Lancet, May 1, 1931, LI, 294-296

This article continues the consideration of joint diseases under the heading of Diseases about the Joints in Children, including rickets, scurvy, congenital syphilis, and differential diagnosis. Other conditions included are achondroplasia, fragilitas ossium, Mongolian idiocy, cretinism and myxedema, osteomalacia, osteoporosis, osteochondritis juvenilis deformans, Osgood-Schlatter's disease, Köhler's disease, Freiberg-Kohler's disease, and Kienbock's disease

W W WATKINS, M D

Outline of Roentgen Diagnosis (sixth paper) Leo G Rigler Journal-Lancet, May 15, 1931, LI, 320-322

This paper is devoted to Diseases of the Spine, and covers anomalies and deformities, traumatic conditions, infectious diseases, tumors, and iodized oil injections into the spinal canal

W W WATKINS, M D

Outline of Roentgen Diagnosis (seventh paper) Leo G Rigler Journal-Lancet, June 15, 1931, LI, 386-389

This paper includes Normal Anatomy (vascular grooves, sutures, basal structures, convolutional markings), Fractures, Diseases of the Skull, Intra-cranial Conditions (with ventriculography and encephalography), the Sella Turcica, the Mastoids, etc

W W WATKINS, M D

Outline of Roentgen Diagnosis (eighth paper) Leo G Rigler Journal-Lancet, July 1, 1931, LI, 417-420

This paper considers the thorax. It takes up the heart and aorta under methods of examination, the normal heart and aorta, technical points, pathologic changes in the heart and pericardium (including mitral regurgitation, mitral stenosis, double mitral, aortic or hypertensive type, combined mitral and aortic valvular disease, tricuspid and pulmonic

lesions, right heart hypertrophy and failure, generalized cardiac enlargement, congenital heart disease, pericardial effusion, adhesive pericarditis), and pathologic changes in the aorta

W W WATKINS, M D

Outline of Roentgen Diagnosis (ninth paper) Leo G Rigler Journal-Lancet, Aug 1, 1931, LI, 478, 479

CHARLES H DEWITT, M D

ROENTGEN RAY (INDUSTRIAL APPLICATION)

Radiographic Inspection of Metals Herbert R Isenburger Mech Engineering, October, 1931, LIII, 1-8

Radiographic examination is one of the most reliable methods of non-destructive routine testing of the structure of metals. In this work roentgenograms made by means of a penetrating radiation of X-rays are known as "exographs" as distinguished from "radiographs" made by means of gamma-rays obtained from radium or its emanation.

The author believes that X-rays should be employed on steel castings and forgings having a thickness of three inches and less, and that gamma-rays should be used for examination of heavier material. More detail, better contrast, and a shorter exposure time result from the use of X-rays, therefore this form of radiation should be used whenever possible. Radiography is of great value in foundry

and welding practice, as in many cases the possible failure of a casting or forging would cause damage far in excess of the cost of the examination. It has been demonstrated that the undesirable internal conditions in castings fall into relatively few classes, all of which are traceable to definite and simple causes, which can be eliminated by proper foundry practice. It likewise has been shown that when defects have been corrected by proper changes in foundry methods, they tend to stay corrected. Among the undesirable conditions in steel castings mentioned by the author are the following: gas, slag and sand pockets or inclusions, shrinkage cavities or cracks, spongy metal, hot tears, and rupture developed during pressure test.

It is suggested in welding practice that all work should be correlated with the X-ray evidence. Sample welds should be made in scrap pieces of the kind of plate to be used in construction and these should be X-rayed. Production should be delayed until the test films are perfect and the correct procedure determined.

J N ANE, MD

pearances, (2) Those with pronounced dilatation of the ventricles and of the subarachnoid spaces, (3) Those with appearances that point to some pathological change different from that in Group 2.

In 8 patients (47 per cent), the encephalographic appearances were normal.

In Group 2 there were 4 cases (24 per cent). Air persisted in this group for as long as 216 hours and apparently depended on the degree of dilatation of the ventricles.

The third group, comprised of 5 cases (29 per cent), either showed no evidence of the ventricles, or else they were distorted and asymmetrical both in size and location. In addition, patients with pronounced leptomeningeal adhesions were included in this group. The diagnosis of the adhesions was based on the absence of sulci markings.

Notkin concluded, in part, that the persistence of air within the cranium seems to correlate more with the dilatation of the ventricles and of the subarachnoid spaces than with the amount of air injected, and also that subarachnoid dilatations may rarely be seen in roentgenograms taken before the injection of air.

THE SKULL (DIAGNOSIS)

Encephalographic Studies in Cryptogenic Epilepsy J Notkin Archiv Neurol and Psychiatry, July, 1931, XXVI, 115-130

The author's apparent purpose in making this study was to confirm or reject the statements of Fay and others who say that there is a characteristic encephalographic picture in cryptogenic epilepsy. Fay states "There has been noted a characteristic picture obtained by roentgenograms in those patients showing convulsive state a definite change can be demonstrated in the fluid pathways by this method."

Notkin performed encephalography on 17 epileptic women between the ages of 18 and 49, of whom 14 were definitely deteriorated mentally. The results of encephalography were classified in three groups:

(1) Those patients presenting normal ap-

THE SPINE (DIAGNOSIS)

Compression Fracture of the Fourth Lumbar Vertebra of a Calf Tom Hare Jour Path and Bacteriol, July, 1931, XXXIV, 437, 438

A case is reported of a fractured vertebra of a young calf, which appears to be comparable with fracture of the human spine. Careful postmortem studies fail to support the notion, originally advanced by Kümmell, that the lesion is the delayed collapse of an injured vertebral body.

E C VOGT, MD

A Study of Back Complaints in 1,000 Patients Clarence B Francisco Med Bull

Veterans' Administration, September, 1931,
VII, 808-815

Following his first analysis, four years previously, of 1,000 cases with back complaints, the author has re-examined and treated many of these cases for their back conditions. About 75 per cent of thirty-six cases of tuberculosis of the spine died during this four-year period. It was also observed from the roentgenograms that hypertrophic changes around the vertebral joints and calcification of ligaments tended to increase very slowly, if at all.

The outstanding observation, in the author's opinion, is that the cause of spinal disability is, with a few exceptions, located in the lower spine or its attachments to the pelvis. Of the 1,000 cases, fifteen were vertebral fractures, and in those cases in which the cord escaped injury, the results were not painful or the backs weak. The disability complained of was stiffness of the back and areas of anesthesia irregularly distributed over the legs.

Thirty-five cases of developmental lateral and posterior curvatures and thirty-eight cases of residuals of spinal meningitis were observed. One hundred twenty-eight cases were diagnosed arthritis of the spine. The forty-four acute cases showed no evidence of bone or joint changes on roentgenograms and became free from symptoms by removal of foci of infection or by medical treatment. Most of the cases in the arthritic group were infectious in origin. While a small percentage was known to have syphilis, it was observed that anti-syphilitic treatment was of negative or doubtful value when given.

One hundred and twenty-six cases were considered as sacro-iliac joint conditions, and in eight cases of this group partial or definite obliteration of the joint was shown by X-ray. It was noted also that as the degree of obliteration of the joint increased, the pain experienced by the patient decreased. Ordinary sacro-iliac supports afforded definite relief of symptoms in the majority of cases, but a small number seemed to resist all forms of treatment.

There were three cases in which the coccyx had been removed by operation, with indifferent results. None of them had been entirely

relieved, and two had not been improved. Two hundred one cases showed on roentgenograms evidences of congenital anomalies consisting of the following: Sacralization of the fifth lumbar transverse process, elongated fifth lumbar transverse process, spina bifida occulta, six lumbar vertebrae, abnormal angulation of articular facets.

J N ANÉ, M D

THE THYROID (THERAPY)

Serious Thyrotoxicosis in a Basedow Case Treated with Intravenous Injections of Sodium Fluoride Leon Goldemberg and J Horacio Maggi Prensa Méd Argentina, July 10, 1931, XVIII, 169, 170

Goldemberg was the first to introduce the use of fluorides orally or intravenously in cases of hyperthyroidism, or Basedow's disease. He uses sodium and ammonium fluoride orally and sodium fluoride intravenously. He and Maggi present here a case, which in spite of anything done, including one treatment with radiotherapy, continued getting worse. After the second intravenous injection of sodium fluoride, the symptoms gradually subsided until the patient reached normalcy.

The authors' method consists of giving an initial dose of 3 cc and increasing it 1 cc daily until the patient feels better and then decreasing the dose according to the results.

N G GONZALEZ, M D

Congenital Myxedema Radiologic and Clinical Observations B Lunardi L'Ateneo Parmense, May-June, 1931, III, 169-176

The author describes a case, not entirely typical, of myxedema, in a boy 15 years of age, which was studied radiologically and which presented numerous interesting diagnostic questions. To which of the various forms of osteodystrophy was it to be ascribed?

There were lacking the special characters of acromegalia (for example, micromyelia), like-

wise, the signs of multiple fracture and osseous deformity which might suggest an imperfect belated osteogenesis, the special manifestations of Ollier's disease, as well as those of dyscondroplasia, properly so-called, were absent. Nor did rickets come directly into question, although certain streaks of thickening in the metaphysis of the femur, radius, and tibia suggested a rachitic form. Likewise, the alterations of the distal extremities of the ulna and radius were indicative of a rachitic connection. These, however, were not the predominant signs. The character of the epiphyses observed in the radiogram of one of the coxo-femoral articulations suggested a youthful dystrophy of the epiphyses, but, on the other hand, there were absent numerous characteristics of this form of epiphysitis, principally the crushing of the nucleus and its fragmentation in island-like masses.

The picture is undoubtedly that of a hypothyroidism, which has produced or determined retardation of the nuclei of ossification. Lack of proper nourishment may have influenced the course of the disease, but how is a greater involvement of one bone than another to be explained, as seen in the tibia, in which the nucleus of the anterior tuberosity is entirely lacking, while that of the superior is normal?

Solution of the problem, the author concludes, lies in the assumption of a simultaneous development of myxedema and rickets, in the same manner that we find the former disease associated with mongolism. This fact is of interest both to the upholders of the theory of endocrine disturbance in the etiology of rickets and to those who invoke alterations of the thyroid as well as to those who regard the disease as a pluriglandular disturbance.

W W WHITELOCK, Ph D

THE TONSILS

The Radiologic Treatment of Malignant Tumors of the Tonsils E Berven Strah-Tenthalerapie, Sept. 12, 1931, XLII, 113-135

The author divided his cases of malignant neoplasms of the tonsil into four groups

Carcinoma, lympho-epithelioma, sarcoma, and mixed tumors. He analyzes in this paper 42 patients with carcinoma of the tonsil observed for from three to twelve years, and 8 cases of carcinoma treated in 1930, 4 cases of lympho-epithelioma, 35 cases of sarcoma, and 5 cases of malignant mixed tumors. The latter were also observed for from three to fifteen years. In all patients free of symptoms for more than three years the diagnosis was verified by biopsy.

From 1919 to 1927, 42 carcinoma cases were treated. Of these, 33 were ulcerated, 6 were not ulcerated, and 3 presented papillary growth. They all metastasized early. From 1919 to 1924, they were treated mostly by X-rays from the outside and radium screens placed on the tumor itself on the inside. Of 28 cases treated in this manner, not a single permanent cure could be obtained and they were free of symptoms for less than three years. It is mentioned that Coutard is the only one obtaining good results with roentgen rays in this type of patient.

Beginning in 1924, a new treatment technic was used. Radium was applied over three or four fields, one over the neck on the side of the tumor, one over the opposite side, one over the posterior neck, and one over the cheek. Six tubes 11×25 mm, 500 mg-hr each, filtered through 0.35 mm Au + 0.3 mm Pt = 1.1 mm Pb, were placed over a circular area about 5 cm in diameter. The applicator brought the total filtration up to an equivalent of 5 mm of lead. The surrounding tissue was protected by 6 cm of lead. The distance between applicator and skin amounted to 6 centimeters. The depth doses with the applicator were very satisfactory, for instance, about 30 per cent of the surface intensity reached the tonsil from the area on the same side.

The physicist of the institute suggested a new unit to express the dose, the Curie intensity, which is defined as follows. The unit for the gamma radiation intensity is that intensity present at 1 cm distance from a radium applicator containing 1 gram radium element in equilibrium with its products of decomposition and where the source of radiation is filtered in all directions by 0.5 mm

only. The dimensions must be so small that the source of radiation can be considered a point.

With the applicator described by the author, about 30 gram-hours can be applied as total dose on the skin at the same side on which the tumor is located. Through the opposite side 20 gram-hours may be given, about 20 gram-hours through the neck field, and about 10 gram-hours over the cheek area. The daily dose usually does not exceed 6 gram-hours. This means that the total irradiation takes from thirteen to fourteen days. It is sometimes advisable to arrange for intervals in order to avoid systemic reactions. The patient must be carefully observed, of course, during this course of treatment.

If an area receives a total dose of 40 gram-hours applied during six or seven days with intervals of one or two days, giving daily six hours, the skin reaction corresponds to the radio-epidermitis of the French authors. The ulcerating area in the center of the treated field is about 3×3 centimeters. This reaction begins about the middle of the fourth week and is usually healed at the end of the seventh week. With a dose of 30 gram-hours one obtains only reddening and desquamation of the skin without complete ulceration, while after 20 gram-hours there is only an erythema. Incomplete and temporary epilation occurs following 20 gram-hours but becomes complete after 40 gram-hours. The reaction in the tumor corresponds to the epidermitis described by Coutard. It is necessary to watch these reactions very carefully as well as the reduction of the size of the tumor. A second treatment should be given only if there is no further reduction and this will be about four to six weeks after the first series.

In order to take care of the remaining tumor tissue one might continue radium therapy as carried out in the first series or apply radium tubes to the surface, implant seeds into the tumor, or remove it by the endotherm knife.

If surface application to the tumor is decided upon, four radium tubes, about 20 mm long, containing 25 mg radium element filtered through gold and platinum equivalent to 11 mm of lead, are used. The dose varies

from 450 mg -hrs according to the individual requirements. Implantation is carried out by means of radium needles containing 10 mg radium element, having a length of 15 mm, a diameter of 2.2 mm and combined gold and platinum filtration equivalent to 0.9 mm of lead. After application of cocaine the needles are inserted into the remaining tumor mass. The injection of a local anesthetic is avoided if possible. In some cases the endotherm knife was also used. The results obtained were as follows: 28 cases were treated from 1919 to 1924. Sixteen, or 57.1 per cent, were not improved, 5, or 17.9 per cent, were improved, one of these over two years, 7, or 25 per cent, were free of symptoms for from two to seventeen months and died from recurrence. Fourteen cases of carcinoma were treated with the new technic from 1923 to 1927. Four, or 28.6 per cent, did not show any improvement, 4, or 28.6 per cent, were improved, one case living nearly four years, 2, or 14 per cent, were free of symptoms thirteen months and twenty-seven months, respectively, 4, or 28.6 per cent, were free of symptoms for three, four, four and one-half, and five and three-quarters years, respectively. Four cases of lympho-epithelioma were treated during the same period. One was free of symptoms for six months and died from recurrence, 3 are living three, four, and five years, respectively, since the treatment. The lympho-epithelioma, much more sensitive than the carcinoma, was treated with the technic used for sarcoma which will be outlined later. Analysis of the statistics shows the enormous influence of the stage of the disease, while, for instance, 50 per cent of the cases belonging to Stages 1 and 2 remained free of symptoms for three years, there was not one case of primary cure in the group belonging to the third stage.

Thirty-five cases of sarcoma were seen. Among these, 29 tumors were not necrotic, 6 were necrotic (it appeared that the latter was the more malignant type). It occurred mostly during the age-period from twenty to thirty years. A combination of roentgen rays from the outside and radium contact application was applied. In the earlier years the author used moderate potential and aluminum filter,

while lately 160 to 170 KV, 0.5 mm Cu + 1 mm Al, corresponding to a half value layer of 0.85 mm Cu, were employed. In a field of 10×10 , 700 r corresponded to the H E D. Sometimes a different filter combination giving a half value layer of 1.42 mm Cu was used. The H E D corresponded to about 100 r, F S D 40 cm, 10×15 sq cm field of entry. Small doses of from 1/6 to $\frac{1}{4}$ H E D are given first. Quite often the tumor reduces definitely after the first few treatments. The dose is increased only if no further reduction can be obtained by these small doses. One must carefully watch the tissue surrounding the tumor in order to avoid excessive inflammation followed by edema. The patients usually receive during two weeks a total of from 1 to $1\frac{1}{2}$ H E D over one or both sides of the neck.

After the tumor has reduced enough in size, radium application is carried out. As a rule four radium tubes are used of 20 mm length, containing 25 mg radium element. The gold-platinum filter corresponds to 1 mm of lead. Doses of from 250 to 1,700 mg-hrs are applied to the tumor surface. Of 35 cases treated from 1916 to 1927, 6, or 17.2 per cent, were not improved, 4, or 11.4 per cent, were improved from one and one-half to four months, 10, or 28.6 per cent, were free of symptoms but died within three years, 15, or 42.8 per cent, were well for from three to twelve years. The influence of the stage of the disease on the final result is also quite evident in these statistics. The author emphasizes that the surgical removal of the tonsillar sarcoma is rather risky. In four out of seven cases local recurrence developed three weeks after tonsillectomy and in two other cases metastases appeared. Biopsies in this type of tumor should be taken, therefore, with great caution.

Five cases with mixed neoplasms were treated with the same technic as the carcinoma. After the tumor had reduced in size the remaining mass was usually removed by the endotherm knife. Two cases were very radioresistant. Three reduced in size following irradiation and could then be removed. Of these three patients, one is alive four

years, one four and three-fourths years, and one five years, respectively, after the treatment.

In conclusion, the author discusses the difficulties in the differential diagnosis between syphilis and malignant tumor of the tonsil. Very often there may be a combination of both. It is dangerous, however, to wait with the proper treatment in case of a malignancy. One must also remember that anti-syphilitic treatment can reduce the necrosis and the size of a malignant tumor, particularly in cases which have syphilis in addition to the malignancy. The prognosis in these cases seems to be rather poor.

ERNST A. POHLE, M.D., Ph.D.

TUBERCULOSIS (DIAGNOSIS)

Skiagraphy in the Diagnosis of Pulmonary Tuberculosis M. Kesava Pai. Antiseptic, July, 1931, XXVIII, 506-509

In the diagnosis of tuberculous hilus disease, circumscribed pneumothoraces, pleural effusions, and occluded cavities, the X-ray has great advantage over our present-day methods of physical diagnosis. Roentgenography is likewise of value as a means of keeping permanent records of chest conditions at different times in the course of treatment.

In the study of roentgenograms of chest diseases it is absolutely essential that the appearance of the normal chest be known and recognized. Pathologic research has proved that tuberculous pulmonary lesions—healed, healing, or active—are present in the vast majority of adults, especially in the region of the hilus. Therefore, a certain degree of "hilus shadow" can be considered normal for all practical purposes. It should be remembered that the hilus shadow is made up by a number of structures, including bronchi, lymphatic glands, and blood vessels. Fluoroscopic examination reveals information regarding the movements of the diaphragms and chest wall, the lighting up of the apices, and the relative translucency of the lungs during inspiration and expiration.

In the pathologic chest a ground glass appearance on the roentgenogram indicates the

presence of thickened pleura or a very thin layer of effusion. The author advises that in the application of artificial pneumothorax treatment a skiagram of every patient be taken and examined before applying treatment. Pneumothorax collapse is a dangerous procedure to be adopted when there is active disease in the opposite lung, for it is a common experience to find deep disease on the collateral side, as seen on the roentgenogram, when it was not suspected by physical examination. The author briefly discusses the roentgenographic diagnosis of various pulmonary conditions and includes reproductions of roentgenograms.

N G GONZALEZ, M D

The Co-existence of Pulmonary Tuberculosis and Other Intrathoracic Lesions
Alexander Josewich Med Bull Veterans' Administration, September, 1931, VII, 803-807

The author believes that the possibility of the association of tuberculous and non-tuberculous intrathoracic lesions has not received due consideration because of the stress that has been put on the differential diagnosis of these conditions by medical literature in general.

Bronchitis, either of the acute or chronic variety, is frequently found associated with tuberculosis. The presence of prolonged bronchitis should always lead the clinician to suspect the association of frank or marked tuberculosis. In some cases of advanced tuberculosis with associated chronic bronchitis, the diagnosis of bronchitis alone is made, on account of constant failure to find the tubercle bacilli. In attempting to come to a true conclusion in such problems, it is to be remembered that although the roentgen examination shows no dependable evidence of bronchitis the hidden areas of tuberculosis, which may not be detected by physical examination, are at times easily revealed by the roentgenologic examination. In the study of these cases the author emphasizes the necessity of employing the diagnostic triad of time, perseverance, and common sense.

Although subacute and chronic interstitial pneumonitis were accurately described decades ago, these conditions have received especial attention during and subsequent to the war. Confusion resulted in many cases and non-tuberculous lesions were considered tuberculous. Of late, however, the detection of these conditions has served to definitely rule out the existence of tuberculosis in interstitial pneumonitis. While in a series of interstitial pneumonitis the author has found less than 5 per cent associated with tuberculosis, he believes that the possibility of the co-existence of these lesions should be kept in mind.

Diagnosis and Treatment of Renal Tuberculosis Mario Donati Revista Med Cubana, October, 1931, XLII, 1202-1218

According to Lasio, in 10 per cent of cases of pulmonary tuberculosis, urogenital tuberculosis is present, and in from 40 to 80 per cent, renal tuberculosis accompanies a tuberculous lesion elsewhere. Since renal tuberculosis seldom manifests itself save in advanced stages, the author advises the examination of urine for the Koch's organism whenever it is known that a tuberculous infection exists elsewhere. He classifies the lesions as (1) Caseous ulcerative type, (2) nodular type—either circumscribed or disseminated, and (3) fibrous type.

The majority of cases of renal tuberculosis occurs between the ages of twenty and forty years. The infection is usually unilateral for a long time. At an early stage, there is a specific secondary inflammation, either of the ureter, of the bladder, or both. The symptoms are usually as follows: Frequency, pain (either unilateral or bilateral), painless bloody urination, symptoms pointing toward pyelonephritis or pyelonephrosis, and marked acidity of the urine. Cystoscopies and pyelograms are of great help in the diagnosis.

The treatment of choice in unilateral or even in bilateral cases in which the function of the better kidney is good is nephrectomy. Medical treatment does not yield good results.

while lately 160 to 170 KV, 0.5 mm Cu + 1 mm Al, corresponding to a half value layer of 0.85 mm Cu, were employed. In a field of 10×10 , 700 r corresponded to the HED. Sometimes a different filter combination giving a half value layer of 1.42 mm Cu was used. The HED corresponded to about 100 r, FSD 40 cm, 10×15 sq cm field of entry. Small doses of from $\frac{1}{6}$ to $\frac{1}{4}$ HED are given first. Quite often the tumor reduces definitely after the first few treatments. The dose is increased only if no further reduction can be obtained by these small doses. One must carefully watch the tissue surrounding the tumor in order to avoid excessive inflammation followed by edema. The patients usually receive during two weeks a total of from 1 to $1\frac{1}{2}$ HED over one or both sides of the neck.

After the tumor has reduced enough in size, radium application is carried out. As a rule four radium tubes are used of 20 mm length, containing 25 mg radium element. The gold-platinum filter corresponds to 1 mm of lead. Doses of from 250 to 1,700 mg-hrs are applied to the tumor surface. Of 35 cases treated from 1916 to 1927, 6, or 17.2 per cent, were not improved, 4, or 11.4 per cent, were improved from one and one-half to four months, 10, or 28.6 per cent, were free of symptoms but died within three years, 15, or 42.8 per cent, were well for from three to twelve years. The influence of the stage of the disease on the final result is also quite evident in these statistics. The author emphasizes that the surgical removal of the tonsillar sarcoma is rather risky. In four out of seven cases local recurrence developed three weeks after tonsillectomy and in two other cases metastases appeared. Biopsies in this type of tumor should be taken, therefore, with great caution.

Five cases with mixed neoplasms were treated with the same technic as the carcinoma. After the tumor had reduced in size the remaining mass was usually removed by the endotherm knife. Two cases were very radioresistant. Three reduced in size following irradiation and could then be removed. Of these three patients, one is alive four

years, one four and three-fourths years, and one five years, respectively, after the treatment.

In conclusion, the author discusses the difficulties in the differential diagnosis between syphilis and malignant tumor of the tonsil. Very often there may be a combination of both. It is dangerous, however, to wait with the proper treatment in case of a malignancy. One must also remember that anti-syphilitic treatment can reduce the necrosis and the size of a malignant tumor, particularly in cases which have syphilis in addition to the malignancy. The prognosis in these cases seems to be rather poor.

ERNST A. POHLE, M.D., Ph.D.

TUBERCULOSIS (DIAGNOSIS)

Skigraphy in the Diagnosis of Pulmonary Tuberculosis M. Kesava Pai. Antiseptic, July, 1931, XXVIII, 506-509

In the diagnosis of tuberculous hilus disease, circumscribed pneumothoraces, pleural effusions, and occluded cavities, the X-ray has great advantage over our present-day methods of physical diagnosis. Roentgenography is likewise of value as a means of keeping permanent records of chest conditions at different times in the course of treatment.

In the study of roentgenograms of chest diseases it is absolutely essential that the appearance of the normal chest be known and recognized. Pathologic research has proved that tuberculous pulmonary lesions—healed, healing, or active—are present in the vast majority of adults, especially in the region of the hilus. Therefore, a certain degree of "hilus shadow" can be considered normal for all practical purposes. It should be remembered that the hilus shadow is made up by a number of structures, including bronchi, lymphatic glands, and blood vessels. Fluoroscopic examination reveals information regarding the movements of the diaphragms and chest wall, the lighting up of the apices, and the relative translucency of the lungs during inspiration and expiration.

In the pathologic chest a ground glass appearance on the roentgenogram indicates the

to the proteins of their own bronchial secretions. Extensive investigation, however, has failed to produce satisfactory evidence of the existence of a sensitizing protein of the tubercle.

The author reports twenty additional cases of pulmonary tuberculosis associated with bronchial asthma, presenting, roentgenologically, evidences of apical cavitation. Two cases were suggestive of bronchiectasis as an additional complication, based on the X-ray evidence of lower lobe dilatation of the bronchi. Sputum positive for the tubercle bacillus was demonstrated in every case. Cutaneous and intra-cutaneous protein tests, which were made to identify the suspected bacterial allergy, were of little diagnostic value. Following the adoption of the subcutaneous injection method, the reactions obtained were strongly suggestive for bacterial allergic response. This also was abandoned following the production of a pulmonary hemorrhage in one case, with a marked extension of the tuberculous lesion and rupture of the cavity wall. Artificial pneumothorax was considered necessary in this case and when satisfactory compression of the apical cavity occurred, all asthmatic symptoms ceased. This patient has been under constant observation for four years following the pneumothorax and at no time has demonstrated a return of asthmatic symptoms. Although this is the only case in the author's series treated by artificial pneumothorax, he considers the question of the advisability of the employment of artificial pneumothorax in the treatment of severe asthma, either associated with unilateral cavitation of tuberculous etiology, or in severe asthmatic cases of non-tuberculous background in which there is evidence of retained secretions.

J N ANÉ, MD

TUMORS (DIAGNOSIS)

Roentgen Diagnosis of Infected, Intraperitoneal Hematoma Gosta Gräberger Acta Radiologica, 1931, XII, No 66, 15, IV, 152-156

In Upsala, roentgen examination of acute and subacute abdominal cases is very commonly employed. The patients are screened, and the movements of the diaphragms and the appearance of the lungs are carefully observed. Plain films of the abdomen are studied for free gas in the abdominal cavity, distention of the small bowel with gas, the outline of the psoas muscle, and the layers of fat in the flank. A barium enema usually concludes the examination.

Laurell has already reported on the appearance of the lateral abdominal wall in these cases. Normally there are visible in the flank four layers of fat: (1) Subcutaneous, (2) and (3) intermuscular, and (4) subperitoneal. When abdominal or retroperitoneal processes reach the lateral abdominal wall, the hyperemia and edema of the subperitoneal fat cause so much absorption of the X-rays that this layer of fat either becomes much less plainly visible or can not be seen at all.

The author reports the course of a case of acute appendicitis in a man 47 years old. Operation was done twelve hours after the onset of the illness and a gangrenous appendix removed. There was considerable turbid fluid about the cecum, but no bacteria were found in it at microscopic examination.

The patient did not do well, and five days after the operation came to roentgen examination with a diagnosis of ileus. Both diaphragms moved freely. Two dilated loops of small intestine were seen in the lower abdomen. A homogeneous shadow in the right flank displaced the cecum and ascending colon medially. The subperitoneal layer of fat was clearly visible. A diagnosis of intraperitoneal hematoma was made.

The patient became worse and four days later was re-examined under a clinical diagnosis of peritonitis. At this time the right diaphragm showed a marked lagging. The homogeneous shadow in the right flank was unchanged but, from the crest of the ilium to the liver, the subperitoneal layer of fat was invisible. A diagnosis of infected intraperitoneal hematoma was made.

Immediate operation was done. About two liters of coagulated blood without grossly visi-

In like manner, carcinoma of the lung or foreign bodies in the respiratory tract may be found associated with active tuberculosis. While the fibrotic changes which take place about a foreign body should not be considered tuberculous, the possibility of the association should be remembered. Aneurysms, mediastinal tumors, and paravertebral abscesses are other conditions found associated with tuberculous involvement. In the author's opinion, the most evident condition should not be allowed to occupy the entire field in such a manner that associated tuberculous lesions are overlooked.

J N AKE M D

A Case of Tuberculosis of the Third Portion of the Duodenum, Secondary to Tuberculosis of the Adjacent Retroperitoneal Lymphatic Glands Rodolfo Viviani Riv di Patolog e Clin della Tuberculosis, July 31, 1931, V, 521-537

It is well known that tuberculous ulcers may, although infrequently, be located in the duodenum. As a rule, however, these are secondary to pulmonary tuberculosis, a condition accompanied with great frequency by intestinal ulcerative conditions of the same nature, particularly in those parts which are most generously provided with lymphatic apparatus, in which the disease process in question locates itself with predilection. It is a familiar fact, also, that tuberculosis may appear, although rarely, exclusively in the duodenum.

On the other hand, tuberculosis transmitted to the duodenum directly from the adjacent tuberculous glands represents an exceptional anatomic finding, according to the literature.

In establishing the highly anomalous nature of the case which he reports, the author confines himself mainly to radiologic procedure and findings, together with a few clinical data. The anatomo-pathologic aspects are discussed by another investigator in an article in the same issue.

The author's observations demonstrate two noteworthy facts. First, that the duodenal contents may repeatedly and for a long time invade the biliary channels without causing

appreciable lesions; second, the peritoneal serosa does not always react with the customary violence to the invasion of infectious material but may manifest relative tolerance. It is possible for an acute generalized perforative peritonitis to arise, accompanied by a clinical symptomatology, objective or subjective, relatively attenuated and under pathologic conditions permitting the prolongation of life for a considerable time beyond the limits usually imposed by the process in question.

TUBERCULOSIS (THERAPY)

The Effect of the Sea Climate on the Red Blood Picture and Tests for the Climatic Reaction on the Sea in Surgical Tuberculosis M Bracher Strahlentherapie, May 20, 1931, XL, 650-657

Children from large cities brought to the sea shore showed a definite increase in hemoglobin, averaging about 10 per cent. Improvement in the blood picture was also seen in patients with surgical tuberculosis. The sedimentation reaction proved to be a valuable guide in prognosis. The mechanism of the climatologic reaction is discussed.

ERNST A POHLE, M D, Ph D

The Asthmogenic Significance of Pulmonary Cavitation in Tuberculosis Associated with Asthma J T Malone Med Bull. Veterans' Administration, September, 1931, VII, 799-802

The author has previously reported a series of ten cases of active pulmonary tuberculosis and associated asthma in which the presence of pulmonary cavitation suggested an etiologic factor of asthmogenic consideration from the standpoint of an existing bacterial sensitization, produced by a focus of mixed infection in retained cavitary secretions. Demonstration of the existence of bacterial allergy was accomplished in these cases by the marked reaction to the injection of a non-sensitized bacterin of mixed bacterial composition employed in small graduated doses. In this regard Eiman believes that 50 per cent of the patients suffering from bronchial asthma are sensitized.

The results published show that the quantity of sugar present is well within the normal limits during the fasting stage, however, the glycohematic curve, after alimentation, shows a peculiar trend in the descending phase, the sugar content diminishing much more slowly than in normal subjects and persisting in noteworthy quantities even two hours after meals

The author is of the opinion that this factor may possibly be of aid in the diagnosis of doubtful cases of malignant tumors and that a normal glycohematic behavior can almost definitely exclude the diagnosis of a neoplastic growth

Comparative experiments for the study of the influence of the nervous systems lead the author to conclude that stimulation of either system shifts the normal glycohematic equilibrium in the same direction. Other factors, however, such as those present in the stimulation of the vagus nerve by pilocarpine, seem to lend credit to the existence of a parasympathetic excitability in the presence of malignant tumors

L MARINELLI

TUMORS (THERAPY)

Shall It Be Radium or Surgery in the Treatment of Uterine Fibroids? H W Hewitt. Jour Michigan St Med Soc, March, 1931, XXX, 129-131

Reduced to a practical basis, the indications and contra-indications for radium and surgery are as follows: radium may be used in intramural tumors not larger than a four months' pregnancy in women at or near the menopause, in patients whose physical condition has been depleted by hemorrhage, and in all patients in whom surgical measures are contraindicated. Myomectomy is indicated in young women in whom child-bearing is a consideration, it being desirable to preserve ovarian function, and in whom other abdominal pathology necessitates a laparotomy. Hysterectomy is indicated in cases in which tumors are large, cause pressure, have degenerated, are subperitoneal or submucous, and in which adneal disease, corpus cancer, or some lesion

of doubtful nature exists. There is no competition between radium and surgery, each has its own field

(Note—X-ray therapy is mentioned at the outset of the article as the third method of treatment, but it is not discussed.)

W W WATKINS, M D

The Influence of Roentgen Irradiation on the Metabolism of the Jensen Sarcoma A Low-Beer and M Reiss Strahlentherapie, Sept 12, 1931, XLII, 157-159

The authors report the results of their investigations dealing with the metabolism of tumor tissue from one to five days following irradiation. They selected the Jensen sarcoma for their experiments. The tumor tissue was implanted under the abdominal skin of rats. As soon as the tumors had reached the size of a hazelnut, which usually occurred twelve days after the implantation, roentgen rays were applied. The exposure was confined to the tumor proper and the remaining part of the body was carefully protected. In view of the superficial location of the tumor, 120 K V, 4 ma, 30 cm F S D, and 4 mm Al were used. The dose applied in one sitting amounted to 650 r. It appeared that the oxidation processes were considerably decreased following the application of this dose. This was shown by the fact that the glucolysis was considerably increased as compared with non-irradiated tumor tissue.

ULTRA-VIOLET LIGHT

The Effect of Ultra-violet Radiation on Sucrase II—The Rôle of Tryptophan and Yeast Gums G Gorbach and K Lerch Biochem. Ztschr., 1931, CCXXXV, 259-266

On dialyzing a yeast autolysate its sucrase activity increases during the first few hours, but, after 30 hours, it decreases very much and shows a continual gradual and steady loss after 48 hours. In the very beginning of the dialysis the dry residue decreases to a small fraction of its original value, and after 48

ble pus were found in the right side of the abdomen, extending upward under the liver. At microscopic examination bacteria were found in the coagulated blood removed from the abdomen. Subsequent recovery was uneventful.

A L HART, M.D.

Malignant Pheochromocytoma of the Adrenals E S J King *Jour Path and Bacteriol*, July, 1931, XXXIV, 447-452

A hitherto undescribed form of pheochromocytoma affecting both adrenals is reported. Two types of cells were present, typical pheochrome cells and anaplastic cells, with all stages of transition between these types. Metastases were numerous to the soft-tissue organs as well as to the bones.

E C VOGT, M.D.

Experimental Tar Tumors in the White Rat A F Watson *Jour Path and Bacteriol*, May, 1931, XXXIV, 301-306

Skin tumors were produced in two male and two female rats by means of the periodic treatment with a gas works coal tar, each application of tar being preceded by a petroleum ether extract of rat tissues.

The tumors appeared from 415 to 551 days after the first application of tar, and in the males were squamous-cell carcinomas. One animal showed extensive metastases. The tumors in the female rats were of slower growth and only one of these showed local extension.

Inoculations of these tumors into normal rats were unsuccessful.

E C VOGT, M.D.

Intra-articular Endothelioma of the Synovial Membrane Julio Diez *La Prensa Médica Argentina* Sept 20, 1931, II, 487-500

The author begins the discussion by calling attention to the fact that there are only seven reported cases of intra-articular endothelioma in the entire medical literature. He attributes

the rarity of the growth to the fact that accurate diagnosis is difficult, even with the aid of the microscope. In Smith's case Ewing classified it as endothelioma and Mallory as fibro-sarcoma with hyperplasia.

The purpose of the article is to bring out some histologic points which facilitate the diagnosis and to point out clinical facts which have been left out in previous reported cases.

The author makes mention of the fact that X-ray films clarify the diagnosis, but it is difficult to differentiate primary articular sarcoma. According to the author, the latter is more diffuse and grows rapidly. The benign growths should give no difficulty in differentiation.

Several photomicrographs are shown at different magnifications. One X-ray film is reproduced giving the shadow of the tumor. In the discussion of the X-ray findings, it is stated that the anteroposterior view in the author's case was entirely normal, while the lateral view showed the growth plainly.

In the line of treatment the author is in favor of high amputation. No mention is made of the use of deep X-ray or radium.

JOSEPH MALDONADO, M.D.

Multiple Teratomas of the Peritoneum W G Barnard *Jour Path and Bacteriol*, May, 1931, XXXIV, 389-391

This is a case report of an ovarian teratoma with many secondary nodules scattered over the peritoneum.

The patient, 40 years of age, died four months after she first noticed an enlargement of the abdomen. How the dissemination took place was not clear, as there was no direct evidence of rupture of the primary growth.

E C VOGT, M.D.

Blood-sugar Regulation and Vegetative Tone in Malignant Tumors Vittorio Romanin. *Minerva Med*, June 9, 1931, XXII, 870-876

This is an experimental study on the sugar content of the blood of cancerous patients.

ily seen when cases of herpes or neuralgia are treated

While no single therapeutic agent can be a panacea, the ultra-violet rays when properly used by one who understands the biologic effects of irradiation, are found to act as a specific cure in some conditions, when used with other forms of therapy, ultra-violet radiation is certainly a valuable aid

NOT OTHERWISE CLASSIFIED

Roentgen Findings as Evidence in Medico-legal Cases William A Evans Jour Michigan St Med Soc, May, 1931, XXX, 329-339

Contradictions in medical testimony are often credited to bias, prejudice, or actual dishonesty on the part of the witness, yet conflicts in statements many times are based on honest differences in opinion there are certain moot questions regarding which authorities hold opposing views and there are differences in opinion due to variations in quality and degree of training and experience

In roentgenology, errors of inexperience can be grouped in three classes first, interpretation of normal structures as pathologic or traumatic, such as blood vessel grooves on shafts of long bones or skull bones, irregular calcification of costal cartilages, variation in rib density due to overlying pulmonary shadows, second, interpreting anomalies or variations in structure as disease or injury, such as accessory tarsal scaphoid or prehallux as fracture, non-united astragaloïd tubercle as fracture (true fractures do occur at this point), hamstring sesamoids as avulsed fractures or loose bodies in knee joints, sesamoid at the acetabular margin as fracture of the ilium, occult spina bifida as fracture, rudimentary ribs at the first lumbar as fractured lateral processes, bipartite carpal scaphoid as fracture, third, interpreting pathologic or disease changes as injury or acute trauma The most common mistake in this last group is in interpreting chronic inflammatory changes in the spine as being due to injury, or the de-

formity of Pott's disease as due to trauma Other sources of misinterpretation are the connection of trauma with malignancy, and the relation of trauma and arthritis

The increasing burden being placed on employers for the medical care of their injured help and the resulting compensation will necessitate action on their part to reduce the number of claims or to lessen the awards Comprehensive preliminary examinations will become necessary, which will involve, in addition to careful physical examinations, roentgen studies of the chest and spine

Eunuchism of Feminine Type Diabetes Insipidus Thyroid Insufficiency Hypophysis Diencephalic Cachexia Mario Schteingart and Alberto Arnaudo Prensa Méd Argentina, Aug 20, 1931, XVIII, 351-357

The authors present a case of a man 34 years old with this complex syndrome At the age of five, following pneumonia, he grew very rapidly but remained below normal mentally When 16 years of age, he developed polydipsia and polyuria, urinating as much as seven quarts a day His whole physical development was feminine in type, the genital organs atrophied, there was diaphysio-epiphyseal hypertrophy, with osseous transparency, articular hyperextension, myxedematous infiltration, dry, hard hair, acrocyanosis and cold extremities, low metabolic rate, gradual loss of weight, etc A roentgenogram showed a rectangular sella turcica with hypertrophy of the postclinoïd apophysis The patient was under observation for three years and during that time there was a gradual loss of weight, the general condition growing worse

N G GONZALEZ, M D

Psychic Regulating Apparatus Psychic Disturbances (Activity, Emotions, etc) in Mesocephalic and Diencephalic Hypophysial Lesions Armando Camauer Prensa

hours it decreases only slightly. The tryptophan content determined spectrophotometrically follows the same sort of curve. During the first hours of dialysis the activity per unit of dry weight runs parallel to the changes in tryptophan content, and the striking fall in activity after 30 hours is accompanied by a similar drop in tryptophan. The yeast gums, unlike the tryptophan, do not have a region of selective absorption, though the shorter the ultra-violet wave the more strongly it is absorbed. At a wave length of 270 m μ the gums have only 1/630 the absorbing capacity of the tryptophan. The inactivation of the sucrase is independent of changes in the gum content.

CHEMICAL ABSTRACTS

Fluorescent Studies on Pathogenic Fungi in Various Spectral Ultra-violet Lights G H Klovekorn and Otto Gaertner Strahlentherapie, 1931, XLI, 370, 371

The fluorescence of six micro-organisms was studied for the lines 3,660, 3,120, 3,020 and 2,650 Ångströms. While all showed fluorescence with all lines examined, 3,660 Å proved to give the best results. *Mikrosporon audouini* and *Achorion quinckeanum* showed the strongest fluorescence. For the diagnosis of mikrosporia this line is, therefore, most suitable.

ERNST A. POHLE, M.D., Ph.D.

Ultra-violet Radiation V C Sudarsanam Antiseptic, July, 1931, XXVIII, 531-539

The sun was worshipped by the earliest tribes in history and even to-day holds a prominent place in the religious rites of many of the older races. Hippocrates established a health temple to Aesculapius, God of the Sun, Medicine, and Music. The priests, who were also physicians, used the natural agencies of air, light, and water in the cure of diseases and the pursuit of both physical and mental culture. Up to about fifty years ago, the virtues of sun, air, and light were forgotten. The author thus reviews the history of ultra-violet radiation.

of ultra-violet rays

may be divided into reactions of degradation, synthetic reaction, and double decomposition. The absorption phenomenon of the ultra-violet ray may be considered as one of the most important of its physical properties. Ozone absorbs ultra-violet rays very strongly. All glasses that contain metals of high atomic weight absorb most of the rays. "Vita glass," containing a large proportion of quartz, has been used in hospitals because of its property of transmitting most of the ultra-violet rays of sunlight.

In the presence of ultra-violet rays a lighted candle glows a bright blue, liver shows an intense yellowish fluorescence, suprarenals an orange red, and cerebral cortex a yellow. This property is especially valuable in distinguishing pearls. Japanese-cultivated pearls give a yellowish fluorescence, oriental pearls appear bluish, and artificial pearls show no fluorescence.

The theories advanced to explain the mode of action of ultra-violet radiations are as follows: (1) That the autonomic nervous system is directly influenced, (2) that rays penetrating as far as the capillaries of the corium are absorbed by the blood, (3) that some substance formed in the epidermis acts as a hormone. Continued irradiation of the skin produces pigmentation. Certain changes take place in the skin as a result of the absorption of ultra-violet rays. It has been proved that these rays convert the cholesterol in the skin into Vitamin D, which stimulates calcium, iron, and phosphorus absorption.

During general irradiation of the body there occurs dilatation of the surface capillaries, and a comparative disengorgement of internal vessels results. Blood serum and blood corpuscles absorb all rays less than 4,500 Å. There is a slight increase in the red and white cells and in hemoglobin. Also, an increase in the immunizing and bactericidal properties of the blood occurs. Reflex contraction of the involuntary muscles results under irradiation, and this property has been tried in some cases of constipation, with benefit. Loss of appetite is likewise relieved by irradiation through the stimulation of the digestive glands. The analgesic effect of the rays is more pronounced with the carbon arc and can be read-

ily seen when cases of herpes or neuralgia are treated

While no single therapeutic agent can be a panacea, the ultra-violet rays when properly used by one who understands the biologic effects of irradiation, are found to act as a specific cure in some conditions, when used with other forms of therapy, ultra-violet radiation is certainly a valuable aid

Psychic Regulating Apparatus Psychic Disturbances (Activity, Emotions, etc) in Mesocephalic and Diencephalus Hypophysial Lesions Armando Camauer Prensa

Méd Argentina, July 30, 1931, XVIII, 249-255

The purpose of this paper is to show that there are areas in the brain which control the psychic part of human beings. The author reviews cases presented by other neurologists which tend to prove that in lesions of the tubero-infundibulo-hypophyseal region there are frequently found disturbances of psychic activity without any alteration of the intellectual and mental part. The disturbances are marked psychic retardation, changes in character and disposition, and a marked oscillation from gay to sad and vice versa. The author believes that we can conclude that there exists in the region of the third ventricle, in the periventricular and mesocephalic constellation a regulatory apparatus of psychic function. He presents the case of a man 65 years old, with a family history of syphilis, who came to him because of heaviness in the leg and psychic disturbances. A radiograph showed the presence of a lesion pressing down on the sella turcica. The Wassermann reaction was ++. The conclusion was syphilis.

The Modification of the Permeability of the Cell Membrane by the Combined Effect of X-rays and Photochemical Catalysts
Lydie Tsebrikow Arch Intern Méd Exper., 1930, V, 641-648

The photochemical catalysts, colloidal Fe, colloidal Ag, or colloidal Au, appear to augment the effect of X-rays upon living tissues, both normal and cancerous. The permeability of the cell membrane is increased and the production of photochemical reactions is facilitated. The effect is not produced by trypan blue or trypaflavine.

An Experimental Study of the Natural Widths of the X-ray Lines in the L-series Spectrum of Uranium John H Williams Phys Rev, 1931, XXXVII, 1431-1442

The half widths at half maximum of the

rocking curves in parallel positions of the double X-ray spectrometer with calcite crystals reflecting in the first order have been investigated as a function of wave length. This function is shown to be linear. The rocking curves of $U\text{ L}_\alpha$ in three different anti-parallel positions of the instrument give a natural width practically independent of the dispersion. The natural widths of $U\text{ L}_\alpha$ and $U\text{ L}_\beta$ show no dependence on voltage. The half widths at half maximum of 12 lines in the $U\text{ L}$ -series spectrum are given. The results are discussed from classical and quantum theory points of view.

Effect of Chemical Combination on the X-ray Spectra of Copper E A Owen and T E Williams Proc Royal Soc (London), 1931, A, CXXXII, 282-295

The K_α doublet of Cu in Cu and its oxides and in a number of intermetallic compounds and solid solutions has been investigated. In all cases there was no change found in the wave length of the $K_{\alpha 1}$ line, or in the separation of the lines in the doublet. It is pointed out that whereas these results are probably true for the intermetallic compounds and solid solutions, they do not hold for the oxides of Cu because of the decomposition that takes place when the latter are placed on the target of an X-ray tube. The positions of the K absorption edges of Cu in the same substances together with a number of inorganic compounds of Cu were determined. The edge in Cu and in the cuprous salts corresponds to the wave length 1377.4 X U and was the same as that obtained with the intermetallic compounds and solid solutions. In all the inorganic cupric salts the edge had moved toward the shorter wave lengths. The shift amounted on the average to 11 X U, which corresponds to 71 v. When an electron is removed as in the formation of cupric compounds a re-arrangement of the remaining

Action of Low-speed Electrons on Photographic Emulsions R E Burroughs Rev Sci Instruments, 1931, II, 321-328

Electrons from a heated cathode were accelerated by a potential to an anode containing a slit. The electron beam passing through the slit was focused by a magnetic field on the photographic emulsion being studied. The experiments performed brought out the following facts: (1) No electron impacts were recorded when the electron beam was not distinctly defined by a visible radiation from the residual gas, (2) the lowest voltage recorded in each case was the lowest energy electron that would produce a visible radiation in the residual gas of the electron tube, (3) the lowest potential which would cause the electron to render the photographic plate developable was determined by the composition of the residual gas and its pressure and in no way indicated that it was related to a characteristic of the photographic emulsion.

The conclusion is drawn that the exposure produced on a photographic emulsion is not due to the sensitive grain receiving the electron's energy directly, but is due to the radiations excited by impacts of the electrons with the residual gas.

CHEMICAL ABSTRACTS

Scattering of X-rays in Argon G Herzog Ztschr Physik, 1931, LXIX, 207-234

The variation with scattering angle of the intensity of X-rays scattered in A is investigated photographically. The results agree with theoretic calculations of Waller and Hartree and confirm the atom model assumed by them. Herzog questions the validity of the analysis by which Compton deduced from experiments on X-ray scattering the distribution

electrons takes place, which causes a change in the energy of the electrons in all the orbits, including those of the K group. Thus the energy necessary to eject a K electron is increased, causing the K absorption edge to move to a shorter wave length. If the formation of an intermetallic compound involved two Cu electrons it would be revealed by a shift in the absorption edge. Since there is no shift the Cu atom in intermetallic compounds must be in the cuprous state.

CHEMICAL ABSTRACTS

The Nature of the Radiations Active in the Phenomena of Photosensitization Jean Cuzin Bull soc chim biol, 1930, XII, 1401-1409

Eosin and methylene blue exert a tonic effect upon the isolated rabbit intestine which interferes with the mild effect of radiation. Hematoporphyrin is sensitive to the entire range of the spectrum studied, but is less sensitive in the yellow, green, blue, and ultraviolet.

CHEMICAL ABSTRACTS

Further Investigation of the Magnesia-zircon Series Based on X-ray and Microscopic Examination A L Roussin and J H Chesters Trans Ceram Soc, England, 1931, XXX, 217-224

Ignited mixtures of magnesite and zircon were found to contain at least two additional minerals, occurring in maximum amounts in the 20-80 and 50-50 mixtures by weight. The mineral found in the 20-80 mixture was similar to zircon microscopically, but had a different X-ray pattern.

CHEMICAL ABSTRACTS

Influence of Chemical Binding on the X-ray Absorption Spectrum Richard Swinne Wiss Veroffentlich Siemens-Konzern, 1931, X, No 2, pp 89-94

It is known that the X-ray critical absorption discontinuities of an element sometimes

exhibit varying degrees of fine structure, depending on the chemical combination. The author points out that London's theory of chemical binding predicts for some cases such energy terms as will account for the fine structure, but that these will not be obtained with polar binding or with neutral free atoms. It is also known that rhombic S is an exception to the general rule that the wave length of the absorption discontinuity of an element in the uncombined state is generally longer than when the element is combined. The author attributes this to the high degree of association of rhombic S.

CHEMICAL ABSTRACTS

X-ray Investigations on the Crystal Structure of Hardened Steel Einar Ohman Jour Iron Steel Inst, London, 1931, advance copy No 12, 19 pages

An X-ray study of quenched steels confirmed the existence of the tetragonal phase, the axial ratio of which increased with increasing C content. From a consideration of these data it is concluded that martensite consists of a solid solution of C in body-centered Fe. On effective quenching the tetragonal phase has the same composition as the parent austenite, as proved by the direct relationship between C content and space-lattice dimensions. It appears probable that the C atoms dissolved in α -Fe form a complex substitutional group in which two C atoms replace one Fe atom. On tempering, the tetragonal phase decomposes continuously with a progressive decrease in axial ratio. The causes of the hardness of martensite are discussed. Forty-seven references are included.

CHEMICAL ABSTRACTS

X-ray Investigation of Certain Nickel Steels of Low Thermal Expansion G Phragmen Jour Iron Steel Inst, London, 1931, advance copy No 14, 10 pages

Precise measurements of the lattice dimensions of Ni-Fe alloys at various temperatures proved that the low coefficient of expansion of alloys containing about 36 per cent Ni is a

property of the face-centered cubic lattice of this compound and is, therefore, not due to a two-phase reaction. The study was made on alloy strips, which could be heated electrically, in a camera utilizing the Bragg focusing principle. At room temperature the maximum lattice parameter occurs in alloys containing about 38 per cent Ni. It is suggested that the specific-volume anomaly may be connected with the anomaly of expansion.

CHEMICAL ABSTRACTS

Acetylene Electrocondensation by Means of β -rays W Mund and J C Jungers
Bull soc chim Belg, 1931, XL, 158-176

In the electrocondensation of C_2H_2 with β -rays, the ratio M/I is equal to 26. A general theory of radiochemical phenomena has been developed. A crystalline structure with complex ions is proposed to explain the properties of the acetylene polymerization product and its mode of formation in the presence of inert gases.

PHYSICAL ABSTRACTS

The Aging of Ions in Air and Nitrogen
John Zeleny Phys Rev, Sept 1, 1931,
XXXVIII, 969-976

Previous work on the mobility of aged ions in air has been extended to the measurement in air and in nitrogen of mobilities of ions at different short ages. The ions were produced by alpha-rays directly in the field used for their measurement, and the average age was obtained from the time taken by the ions to cross between the two electrodes. In air containing 4 mg of water per liter, both kinds of ions of short age had the same mobility of 20 $cm^2/volt\ sec$, while at an average age of 0.18 sec the negative ions moved 8 per cent faster than the positive. In air partially dried by KOH, the mobility of the negative ions decreased from 2.3 (above units) at 0.004 sec to 2.1 at 0.34 sec, while the positive ion mobility decreased from 2.0 at 0.004 sec to 1.7 at 0.26

sec. In air dried by aid of liquid air traps, the negative ion mobility decreased from 2.44 at 0.004 sec to 2.35 at 0.28 sec. The positive ions in this dry air were found to be very sensitive to minute changes in conditions that had no effect on negative ions. These changes are supposed to arise from small traces of some unknown impurity. Positive mobilities as high as 2.3 at 0.05 sec were obtained.

The new information is applied to the explanation of the previous results for older ions. No transformation of one type of positive ion into another single type, as observed by Erikson, was found under the conditions of these measurements. The ions were all found to have the same mobility at the shortest ages, but with increase of time the ion mobilities became spread over a range of values, the numbers given above corresponding to the peak of the distribution curves. The nitrogen used contained 0.3 per cent of oxygen. The negative ions of short age all had a very high mobility which could only be roughly estimated as of the order of one hundred. With increase of age these fast ions gradually transformed into slower ions which were not all alike and had a peak mobility that decreased from 3.0 at 0.04 sec to 2.5 at 0.25 sec. The fast negative ions presumably remain free electrons for a large portion of their path, and since their mobility does not appear to change with time, it is necessary to suppose that these ions alternate frequently between being free electrons and monomolecular ions, but after more molecules become attached, the ion can no longer revert to the electron stage. The positive ions in nitrogen were always contained in one group only, the peak mobility of which ranged from 2.2 at 0.007 sec to 1.8 at 0.17 sec. The slow decrease of mobility of the ions with age and the large effect of slight changes apparently of gas composition upon the rate of this decrease for positive ions especially, indicate that the ions are gradually undergoing change of size owing to the accretion of scarce molecules or the exchange of such molecules for those which first gather about the central charge to form an ion cluster.

Transition Effect of Cosmic Radiation Shown by Varying the Absorbing Medium.
E Steinke Physik Ztschr, 1930, XXXI, 1019-1022

A new differential method of detecting cosmic radiation is described. Measurements of the absorption coefficient for this radiation traversing Pb, Fe, Al, water, and paraffin show that Fe and the heavier elements appear to absorb anomalously, the absorption coefficient diminishes with increasing thickness, probably because of a secondary radiation excited by the cosmic radiation in the heavier atoms. An unsuccessful attempt was made to detect scattered electrons by means of a magnetic field.

Comparison of Viscosity and Molecular Arrangement in Twenty-two Liquid Octyl Alcohols G W Stewart and R L Edwards
Phys Rev, Nov 1, 1931, XXXVIII, 1575-1582

A comparison is made between the X-ray diffraction halos of 22 octyl alcohols and their corresponding viscosities and an unmistakable correlation found. The assumptions are that the halos indicate periodicities, that the periodicities may be interpreted as structural in the "cybotactic" groups, and that the relative diffraction intensity of the halos computed by assuming crystal structure may be used to estimate roughly the perfection of the liquid groups. It thus is shown that there is a correlation between the coefficient of viscosity and the perfection of grouping in the direction of the length of the chain molecules. This corresponds with the reasonable view that the viscosity within the liquid groups is caused by longitudinal slippage. Moreover, since the groups at any instant occupy a large fraction of the volume of the liquid, this viscosity is an important part of that measured. This interpretation accounts for the negative temperature coefficient of the viscosity, since the size of the groups decrease with temperature.

The experiments and conclusions are in accord with Andrade's theory of momentary

The Diffraction of X-rays in Organic Mixtures Alfred Wesley Meyer
Phys Rev, Sept 15, 1931, XXXVIII, 1083-1093

An examination was made by an X-ray diffraction ionization method of the following mixtures: ethyl alcohol-methylcyclohexane, butyl alcohol-ortho-dimethylcyclohexane, quinoline-phenol, paraldehyde-cyclohexane, tetranitromethane-cyclohexane, and phenol-water. All of these mixtures are totally miscible, except the last, phenol-water, which is totally miscible at higher temperatures and is an emulsion in some proportions at ordinary temperatures. In all cases of solutions the diffraction exhibits a single major peak which has an angular position between the positions of the peaks of the constituents and shifts directly with the concentration but in general not in a linear manner. There is in some cases definite indication of the existence of secondary peaks corresponding to those found in the pure constituents but these also shift. In the single case examined of an emulsion, the major peaks of both constituents were found and the intensity of each varied directly with the concentration of that constituent. The results indicate that in a solution there exists a single type of cybotactic group and that the molecules of both constituents enter this formation. The length of the most probable

ence periodicity in the group depends upon the proportion of the liquids involved. The emulsion contains two types of cybotactic groups corresponding to the two constituent liquids. These conclusions suggest a very fundamental differentiation between solutions and non-solutions. This differentiation between solutions and non-solutions does not depend upon the fineness of the separation of either liquid. A solution exists when and only when the components, instead of having their individual space molecular groupings, conspire to form a single type of cybotactic group. With this description, the nature of a solution has a similarity to that of a crystal and has a definite concept.

THE AUTHOR

traced in some cases to certain diagram lines which had not heretofore been thoroughly investigated, and that the presence of the satellites beyond these limits is in general to be doubted, at least as far as present accuracy and sensitivity of observation are concerned. The existence and sharpness of these limits seem to be in conflict with the Wentzel-Druyvesteyn double-ionization theory of the origin of the satellites. A table of new wave lengths is included.

THE AUTHOR

Two New Methods of Interpreting Photographs Made with Convergent X-rays
O Kratky Ztschr Krist, 1931, LXXVI, 517-524

A description of two methods is given in one of which the crystal and film remain stationary, and the incident beam converges to a point on the crystal face, the angle of convergence being about 30° . The second method involves a double exposure, with a slight shift in the slit system.

Upper Atomic-number Limits for Satellites of the X-ray Line $L\beta_2$, R D Richtmyer Phys Rev, Nov 15, 1931, XXXVIII, 1802-1807

The region of the X-ray spectrum in the immediate neighborhood of the line $L\beta_2$ has been photographically studied for the elements of atomic number 50, 51, 52, 53, 56, 58, and 60, with a view to determining more precisely the atomic number ranges of the satellites (five in number) of $L\beta_2$. It appears that these ranges have clearly defined upper limits in the cases of all but one of the satellites of $L\beta_2$, and that the previously supposed presence of these satellites beyond these limits, approximately atomic number 53, can be

The Directional Distribution of Photo-electrons from Short Wave Roentgen Rays
Erich Lutze Ann Physik, 1931, IX, 853-864

The distribution of photo-electrons liberated by short X-rays was observed with a Wilson cloud apparatus using A in the expansion chamber. The observed distribution agrees with the theory.

CHEMICAL ABSTRACTS

A New Experiment Bearing on Cosmic-ray Phenomena L M Mott-Smith and G L Locher Phys Rev, Oct 15, 1931, XXXVIII, 1399-1408

This new experiment consists in combining a Wilson cloud expansion apparatus with Geiger-Muller electron-counters in a manner which allows the simultaneous study of individual cosmic-ray particles by the two methods. Its purpose was to see whether the coincidence effect in electron-counters is actually caused by the passage of an ionizing particle through them as has been generally assumed. This was considered desirable because it was felt that the several conflicting cosmic-ray experiments could perhaps be more satisfactorily explained by assuming the coincidences to be produced by photons. In this work a series of expansion photographs was taken under experimental conditions which allowed a definite correlation of an ion-track appearing in

the expansion chamber with a discharge of a Geiger-Muller counter. It was found that the discharges of a counter due to cosmic radiation are accompanied by ion-tracks resembling those due to fast β -rays from radio-active sources. This result means that, in accord with previous beliefs, the coincidence effects are caused by ionizing particles. The best assumption we can make at present appears to be that these are high-energy electrons. The possibility that these effects are due to photons appears to be excluded, so that the reconciliation of the conflicting experimental data in this field will have to follow other lines.

THE AUTHOR

Dispersion of X-rays in Calcite Louis A Pardue Phys Rev, Nov 15, 1931, XXXVIII, 1808-1815

The dispersion of X-ray in calcite has been investigated. The total radiation and the $K\alpha_1$ line from a molybdenum target tube operated at about 44,000 volts were used in different experiments. The decrement of unity in the index of refraction for the $K\alpha_1$ wave length was found to be $(2.001 \pm 0.009) \times 10^{-6}$. This does not agree with the value computed on the Drude-Lorentz theory. The specimen was a right prism with the optic axis parallel to the 90° refracting edge. No evidence was found for double refraction. The intensities of $MoK\alpha_1$ radiation reflected from calcite mirrors were measured for angles in the neighborhood of

the critical angle. These experimental values were compared with the values computed on the basis of Thibaud's modification of Fresnel's equation and found to be in fair agreement.

THE AUTHOR

The Structure of Soft X-ray Lines William V Houston Phys Rev, Nov 15, 1931, XXXVIII, 1797-1801

The experimental work on soft X-rays has shown that the lines produced by the bombardment of a solid target are much broader than those emitted by a vapor. This is due to the fact that the upper level is not sharp. The breadth and the shape can be calculated from the various models which have been used for describing the behavior of electrons in metals. The free electron model gives a line which has a sharp edge on the short wave length side. This is not observed in Be. The calculated width, however, agrees well with the observed. The bound electron model gives a more satisfactory shape for Be, but the width cannot be exactly determined. The comparison of the line shapes calculated on the basis of these two models with that observed in Be shows that, although the free electron model gives a good approximation to the zero point energy, the distribution of energy levels is strongly affected by the periodic potential in the crystal.

ROENTGENOLOGIC EXPLORATION OF THE MUCOSA OF THE GASTRO-INTESTINAL TRACT*

By THE COLE COLLABORATORS

FOREWORD TO AN ADDRESS PRESENTED BY INVITATION TO THE THIRD INTERNATIONAL CONGRESS AT PARIS

MR PRESIDENT On behalf of the roentgenologists of America I wish to express the appreciation of my colleagues for the honor you have done our country in assigning to America a consideration of this very important and controversial problem Realizing as I do that the literature would indicate that very little consideration has been given to this subject by them, this honor is all the more appreciated

To the American delegates, both my associates and myself wish to express our great appreciation of the honor done us in this assignment

To the members of the Congress I wish to say that the article here presented is merely a resumé of data that have been assembled in a far more extensive article which will be published serially in *RADIOLOGY*. The complete data will include the reports of personal communications from many of the foremost American roentgenologists, an extensive study of the foreign literature with translations into English, the assembling of material from the various institutions with which I am associated, and the designing and actual construction of apparatus for applying the localized pressure technic. The assembling of these data and preparation of the illustrations could have been accomplished only by the very hearty and loyal co-operation of those who are directly associated with me. This refers to Robert Earl Pound, M D, Russell Wright Morse, M D, Courtenay I Headland, M D, William Gregory Cole, M D, and Ames W Naslund, M D, who are herein referred to as The Cole Collaborators, and under which title this complete article will be published.

The honor of presenting this subject would undoubtedly have fallen to the late Preston M Hickey had he lived, and considering this fact, and the great honor and respect in which Preston M Hickey was held not only by American roentgenologists but by roentgenologists throughout the world, this complete

*Presented at the Third International Congress of Radiology, Paris, July, 1931, by Lewis Gregory Cole, M D

ROENTGENOLOGIC EXPLORATION OF THE MUCOSA OF THE GASTRO-INTESTINAL TRACT*

By THE COLE COLLABORATORS

FOREWORD TO AN ADDRESS PRESENTED BY INVITATION TO THE THIRD INTERNATIONAL CONGRESS AT PARIS

MR PRESIDENT On behalf of the roentgenologists of America I wish to express the appreciation of my colleagues for the honor you have done our country in assigning to America a consideration of this very important and controversial problem Realizing as I do that the literature would indicate that very little consideration has been given to this subject by them, this honor is all the more appreciated

To the American delegates, both my associates and myself wish to express our great appreciation of the honor done us in this assignment

To the members of the Congress I wish to say that the article here presented is merely a resumé of data that have been assembled in a far more extensive article which will be published serially in *RADIOLOGY*. The complete data will include the reports of personal communications from many of the foremost American roentgenologists, an extensive study of the foreign literature with translations into English, the assembling of material from the various institutions with which I am associated, and the designing and actual construction of apparatus for applying the localized pressure technic. The assembling of these data and preparation of the illustrations could have been accomplished only by the very hearty and loyal co-operation of those who are directly associated with me. This refers to Robert Earl Pound, M.D., Russell Wright Morse, M.D., Courtenay I. Headland, M.D., William Gregory Cole, M.D., and Ames W. Nashlund, M.D., who are herein referred to as The Cole Collaborators, and under which title this complete article will be published.

The honor of presenting this subject would undoubtedly have fallen to the late Preston M. Hickey had he lived, and considering this fact, and the great honor and respect in which Preston M. Hickey was held not only by American roentgenologists but by roentgenologists throughout the world, this complete

*Presented at the Third International Congress of Radiology, Paris, July, 1931, by Lewis Gregory Cole, M.D.

article will be assembled in a bound volume as a memorial to the Dean of American roentgenology, Preston M Hickey

The title "Roentgenologic Exploration of the Mucosa of the Gastro-intestinal Tract," which was assigned to us, is an unusual one, probably due to the translation from one language to another, but the term "exploration" is so applicable to the early history of this problem in which the participants were real explorers, that I am more and more pleased with the title as it was assigned

HISTORY

Reviewing the development of gastro-intestinal roentgenology as presented by Dudley Roberts before the American Gastro-enterological Association in 1928, we find that "Hemmeter must be given credit for first suggesting a way of visualizing the stomach, by means of his intra-gastric bag filled with lead solution. These experiments were not successful but were the first attempts State Normal School, Baltimore, Maryland."¹

Wolf Becker, in 1896, reported on his experiments with animals, in which experiments he attempted to fill loops of intestine and the stomach with lead solution. These experiments were not successful but were the first attempts at the use of free opaque solutions to make visible the lumen of the hollow viscera.

H P Bowditch, Professor of Physiology at Harvard University, in the Fall of 1896, suggested to Walter B Cannon that the X-rays be used as a means of studying deglutition under normal conditions. This was the beginning of Cannon's famous researches on the motor phenomena of the esophagus, stomach, and intestines. The first public demonstration of movements of the alimentary tract by use of the new method was given in Boston, Dec 29, 1896. At this time the phenomenon of deglutition as exhibited by the goose when swallowing capsules containing bismuth subnitrate was informally demonstrated by means of the roentgen rays before the American Physiological Society. The first report of the studies of the stomach of the cat was made before the American Physiological Society, May 4, 1897. Cannon was the first to use free bismuth in an opaque meal in animals, and this meal consisted of subnitrate of bismuth mixed with bread which had been softened to a mushy mass by milk, hot water, or thin gravy. Cannon, himself, states that the first published account of the use of bismuth subnitrate to make visible the alimentary tract was given by Rumpel, who, on April 20, 1897, published a report of rendering a pathologically dilated esophagus visible by pouring into it 300 c.c. of a 5 per cent suspension of bismuth subnitrate.²

¹We have in our possession a photographic copy of a letter from W C A. Hammell verifying Hemmeter's claims.

²We have recently received a personal letter from Dr W B Cannon confirming the accuracy of these statements. He has recorded the early history of his work in an article written in 1913 ("The Early Use of the Roentgen Ray in the Study of the Alimentary Canal," Jour Am. Med. Assn., Jan. 3, 1914, LXII, 1-3).

Apparently independently and contemporaneously, on June 12, 1897, and July 24, 1897, before La Société de Biologie, Roux and Balthazard presented their first reports of the use of the bismuth opaque meal in the study of the motor function of the stomach. Their full report, published in 1898, included studies of the stomach of frogs, dogs, and man by use of the bismuth opaque meal. Their studies are epochal because these writers were apparently the first to study the *human stomach* by means of an opaque meal, using 15–20 grams of subnitrate of bismuth suspended in 100 grams of water or syrup, and secondly, because they were the first to conceive the value of cinematographic study and devised a single plate-changing apparatus which enabled them to make roentgenograms of the frog's stomach at regular intervals during the progress of the peristaltic wave. Although incomplete, their observations of the gastric motor phenomena in man were exceptionally accurate.

Francis H. Williams, of Boston, deserves far more credit than he has ever received for his early recognition of the value of the roentgen rays in medicine and surgery. Perhaps this is because his extreme reticence has prevented him from claiming it or even accepting it. Williams's book, "Roentgen Rays in Medicine and Surgery," published in 1901, is an early classic. Williams, assisted by Cannon, on Sept. 23, 1899, administered an ounce of bismuth subnitrate in a meal, consisting of a pint of milk into which bread had been broken, to a child ten years of age. Fluoroscopic studies were then made, and twelve tracings made of this and another case at various stages of gastric evacuation and in different postures were recorded in Williams's book in 1901. The findings which are there recorded are remarkably accurate as regards the changes in size, shape, and position of the stomach as the result of respiration, change of posture, and digestion. Williams's Fig. 201 is a reproduction of a tracing which had previously been published in the Transactions of the American Climatological Association, 1898. This was a "cut of a tracing made by means of the fluorescent screen from a girl seven years old, showing the outline of the stomach one hour after a meal of bread and milk containing subnitrate of bismuth."

At the Boston City Hospital, where Williams is an attending physician, he has never allowed the title of "roentgenologist" or "radiologist" to be employed. The appointment is recorded as "physician in charge of the X-ray Department." It has always been his conception that the roentgenologist should primarily be a physician rather than a laboratory worker, and that he should be interested in all phases of medicine rather than limit himself to the making and interpretation of roentgenograms. At the present time the justification of his attitude toward this problem is just becoming recognized. It gives us great pleasure to herewith reproduce an autographed photograph of Dr. Francis H. Williams in recognition of his great wisdom concerning the status of the roentgenological physician.

Einhorn, on April 1, 1899, at the office of Willy Meyer, used the X-ray in

a single case to demonstrate a powder blower which he had designed for applying medication to the gastric mucosa

"In 1898, Holzknecht began using small dose of bismuth in aqueous suspension, especially for the study of the esophagus on a firm basis, but the visualization of the stomach and intestines was not furthered by such meals" (Roberts)

Then for almost half a decade there was a silent era broken only by the contributions of O Kraus and Lommel. A schematic chart (Fig 2) helps one to visualize the time relation of the historical events.

Nearly five years later (1904), Rieder, of Munich, with much more publicity and without giving due credit to Roux and Balthazard and no credit to Williams, advocated the use of a meal, the composition of which was almost identical with that previously described and employed by Williams. As a result of Rieder's announcement, this opaque meal of gruel and bismuth became known the world over as "Rieder's meal."

During the following years, 1905-1909, fluoroscopic exploration of the gastro-intestinal tract, with "symptom-complices" as the criterion on which the interpretation of the findings was based, became the vogue, particularly on the Continent. Until 1909, Austria and Germany led the world in this work and among the leaders the names of Holzknecht, Strauss, Rieder, Schwartz, Kreuzfuchs, Groedel, Albers-Schonberg, Haenisch, and Kienbock are outstanding. Many students from all over the world, and particularly from the United States, were attracted to the clinics of Austria and Germany.

An explanation of this popularity of fluoroscopy and symptom-complices is found in the fact that at this time roentgenography of the moving parts was most unsatisfactory. During these years the mechanics of producing X-rays and roentgenograms had not developed sufficiently so that one could obtain satisfactory roentgenograms of the gastro-intestinal tract. Intensifying screens had been employed for the intensification of the photographic effect of the ray in scientific experiments, but these had not yet come into practical use for gastro-intestinal roentgenography. The only two methods of exciting the X-ray tube were by the static machine and by the coil. Neither the static machine nor the coil, however, was powerful enough to make satisfactory roentgenograms in a sufficiently short period of time to avoid blurring incident to the movement of the gastric peristalsis. The slower movement of the colon rendered roentgenography more practical in this region than in the stomach or small intestine. At one time from fifteen to twenty minutes were required to make an exposure of the abdomen as for a kidney stone. By 1903-04, as a result of gradual improvements in apparatus, the time of exposure had been reduced to fifteen or twenty seconds so that roentgenograms could be made of the kidney stone while its motion due to respiration was stopped. Sufficiently rapid exposure to avoid the motion of gastric peristalsis, however, continued to be impossible. Roentgenograms of the stomach were so blurred that they were of little or no diagnostic value. Both methods

of exciting the tube, however, were sufficiently strong to enable one to observe fluoroscopically the size, shape, and position of the stomach, as well as some of the grosser lesions of the stomach, when present.

In the United States the resurrection and further development of gastro-intestinal roentgenology dates from 1905. In that year, Hulst, who had visited Rieder in Munich, informally presented roentgenograms of the gastro-intestinal tract at the annual meeting of the American Roentgen Ray Society in Baltimore. The following year, as his presidential address before the American Roentgen Ray Society, he presented an illustrated comprehensive paper on the roentgenographic method of examination of the gastro-intestinal tract which was so complete that it furnished a new impetus to the method. Williams had suggested seven years previously. In this paper Hulst accords credit to Williams for giving one ounce of bismuth in emulsion as early as 1897, and it may be this fact to which Williams refers (p. 359 of his book).

The Advent of the Transformer and Screen.—At the same meeting (American Roentgen Ray Society, 1906) at which Hulst resurrected gastro-intestinal roentgenology, Snook first presented the electrical facts upon which he developed and made practical the transformer which superseded the static machine and coil. Snook developed the transformer in 1907, and this, with the improvement and application of the intensifying screen, enabled exposures to be made in a fraction of a second—thus the blur, due to movement of the stomach, was eliminated.

Prior to the advent of the transformer and intensifying screen, bismuth was suspended in a thick gruel which prevented it from filling the crevices between the rugae. When roentgenograms that showed greater detail became available, bismuth was suspended in buttermilk, which allowed the mixture to seep into the spaces between the mucosal folds in a manner that it could not do when suspended in thick gruel. Then, for the first time, routine plates were made which showed the rugae of the stomach. With this technic it was possible to observe any growth that protruded sufficiently deeply into the stomach to cause an irregularity of the contour, which was then termed a "filling defect." It was possible also to note spasm of local regions of the stomach or pressure from without, likewise causing a similar "filling defect." In a filling defect due to spasm (Fig. 3) the rugae were observed within the deformed area, however, in a filling defect caused by a growth protruding into the lumen of the stomach (Fig. 4), the rugae were singularly absent. Thus, as far back as 1908-09, the first of the four fundamental findings that will later be described, namely, alteration in contour, and the fourth of these findings, the pattern of the mucosa, were already considered of paramount importance in the diagnosis and differential diagnosis of gastric cancer. There then ensued a long and bitter controversy concerning the relative value of symptom-complexes observed fluoroscopically and morphology observed roentgenographically as criteria for the interpretation of roentgenological findings into gastro-intestinal diagnosis.

The main contention on the part of those who objected to morphology observed roentgenographically as the proper criterion for diagnosis was that various roentgenograms of the same stomach differ so much in their appearance that a conclusion could not be drawn from the evidence on a single plate. The proponents of the morphologic basis of X-ray diagnosis proceeded to obviate this difficulty by making a series of plates in as rapid succession as possible. As a result, the factor of change in contour that before had been regarded as a disadvantage, proved in reality to be of great assistance. Subsequently this pliability of the gastric wall became the corner stone on which to build roentgenologic gastric diagnosis, and the making of a series of plates in rapid succession was promptly adopted by some observers as a routine procedure and was called "serial roentgenography."

In 1909, Kaestle, Rieder, and Rosenthal attempted to make roentgenocinematographic films of the stomach under the term "bio-roentgenography." They assembled roentgenograms of a normal individual and reproduced these cinematographically to illustrate the normal motor phenomena of the stomach. Through the courtesy of George E. Brewer and William G. Lyle, who was then private physician to E. H. Harriman, the author had the opportunity to observe this roentgenocinematographic demonstration of Kaestle, Rieder, and Rosenthal. This procedure was applied to the study of the motor phenomena of the stomach. Subsequently I was able to find only one cinematographic film which was a reproduction of serial roentgenograms made by their method. With few exceptions, particularly Meyer of Berlin, this method was not accepted on the Continent as a practical method of roentgenological diagnosis of gastro-intestinal lesions.

In 1909 the author began making from ten to twelve plates of the stomach in each of three postures, the erect posture, the prone posture, and the prone oblique posture in which the patient lies on the right side, as a routine procedure for the study of the stomach in every gastro-intestinal examination. To this method he applied the term "serial roentgenography." Because of the frequent intentional and unintentional misinterpretation and misuse of this term, it is best to define here what is meant by "serial roentgenography" as applied to the stomach. Serial roentgenography is a series of eight or more roentgenograms made of the filled stomach in one posture of the individual, these roentgenograms to be made at intervals of from four to ten seconds, so that in this series all of the phases of the gastric motor phenomenon will be depicted. In order to be of value such a series of roentgenograms must be made with the individual in two different postures, the erect and prone, and in two directions, the postero-anterior and oblique. Serial roentgenograms (Figs. 5 and 6) are of limited value unless they are observed on an illumination box of sufficient size so that they may all be observed at once and compared one with another.

During this time the symptom-complex method was used almost exclusively on the Continent. In America, however, during the period of intense

development of the direct method there were many minor skirmishes between advocates of the two methods. The real battle occurred in Chicago at the meeting of the Mississippi Valley Medical Association in 1912. Skinner was the advocate of the Continental method. Selby, also favoring the Continental method, was roentgenologist at the Mayo Clinic at the time, and, acting under instruction, stated that, while the X-ray was useful in examining bones and lesions of the kidney and chest, it was valueless fluoroscopically and otherwise as a method of diagnosis of gastro-intestinal lesions. Your essayist presented a series of roentgenograms in support of his contention on behalf of the direct method. These roentgenograms illustrated characteristic deformities of the lumen of the gut that are caused by certain pathologic lesions, particularly cancers, gastric ulcers, postpyloric ulcers and gall-bladder adhesions, calling attention to the points of differentiation among them. This brought the two methods into direct controversy, which raged for a number of years. Carman, who succeeded Selby as roentgenologist at the Mayo Clinic, rather elaborately described a group of what he called "roentgenologic signs" as a basis for the diagnosis of gastro-intestinal lesions. These roentgenologic signs represented the principles included in the symptom-complexes, but, in addition, included the direct detection of some of the grosser pathologic lesions by fluoroscopic examination. He was the last influential advocate in the United States of the symptom-complex method of diagnosis.

Among the earlier supporters of the direct method of examination, Arial George gave the essayist more support than any other person, particularly in the diagnosis of postpyloric ulcer, and this subject became the storm center of a cyclonic controversy in Boston in 1913.

At the time that the serial method was being established it was noted that the mucosal pattern was of great significance, especially in the diagnosis of organic lesions and the differential diagnosis of malignant lesions from spasm. With the roentgenographic technic it was observed that any growth which protruded into the stomach caused an irregularity of contour known as a "filling defect." Spasm of local regions of the stomach or pressure from without caused a similar defect. In a filling defect due to spasm or pressure, the rugae were observed within the deformed area, however, in a filling defect caused by a growth protruding into the lumen of the stomach, the rugae were singularly absent. Thus, as early as 1909 the first of the four fundamental findings (Fig 4), alteration in contour, as well as the fourth fundamental finding, the pattern of the mucosa (Fig 3), became of paramount importance in the diagnosis and differential diagnosis of gastric cancer.

A special technic was, therefore, developed to accentuate the mucosal patterns. This special technic consisted of sedimentation of bismuth from a thin watery suspension onto the anterior or posterior gastric wall. Details of this technic will be described later. However, at this time we are submitting illustrations to show that the characteristics of the mucosal pattern were even then considered of significance. The roentgenogram illustrated

in Figure 7 was made on October 13, 1910, and represents the essayist's first attempt to demonstrate the pattern of the gastric mucosa by a special technic. The roentgenograms illustrated compare favorably with the more modern methods of observing the mucosal pattern.

For a time both the serial method and the special mucosal technic were used on the same patient in order to determine which would be the more satisfactory to adopt for the routine procedure. The serial method with a moderately filled stomach, although far more extensive and, therefore, more expensive, seemed to us to be of much greater value than the special mucosal technic, and was, therefore, adopted as our routine method of examination. The special mucosal technic was used only as an adjunct in certain specific cases. Serial roentgenography was also applied to the mucosal technic (Fig. 8).

At this time the spirit of the pioneer was rampant and we moved from one field of exploration to another with such rapidity that we could not "get organized." These were grand and glorious days to which all subsequent exploration seems tame. Now as I review the evidence that we then assembled, it seems as though there is little that has been added in the last two decades. In proof of this we are largely illustrating this communication with roentgenograms made during this early period.

History of Roentgenological Methods for Study of the Mucosa.—A thorough comprehension of modern technic as employed by various investigators of the gastro-intestinal mucosa is essential to an understanding and interpretation of their findings. Åkerlund, 1921, rediscovered the direct method and published an extensive monograph on duodenal ulcer in which he discussed at length the deformities of the "duodenal bulb" incident to ulcer. He directed particular attention to the correlation of the morphological changes observed in the roentgenograms and the anatomic-pathologic changes observed in specimens obtained by operation and autopsy. This work created or marked the beginning of a new era in roentgenology of the gastro-intestinal tract as practised by roentgenologists on the Continent. Symptom-complices were forgotten. The direct roentgenological detection of morphologic changes in the wall of the gut became the fashion. This revived on the Continent the same old controversy concerning the relative value of symptom-complices and direct morphology which had been definitely settled in the United States a decade earlier.

Åkerlund mentioned the "method of the thin layer," explaining that by exerting external pressure upon the duodenal bulb all but a thin layer of the opaque contents may be forced out of the cap, bringing to view the markings of the mucosa and ulcer craters which otherwise would be obscured. Bastrup and Rendich, in 1923, published papers dealing with special methods for demonstrating the pattern of mucosal folds in the stomach. These ideas were greeted as a new departure. Many observers became "mucosa conscious." Yet, whenever a certain idea or method becomes the center of inter-

est, it is always wise to look back over the literature to see what is new and what is a revival of someone's previous work

In the following section we shall present chronologically the history of certain technical methods of roentgenologic examination of the gastro-intestinal tract. The general story of the usual methods has been presented in the previous chapter, so, at this time, more detail will be devoted to the technical methods of study of the mucosa.

Rieder, 1904, noticed after a bismuth enema had been injected, and after the patient had been standing for a few minutes, that the bismuth would precipitate out of solution into the dependent part of the haustral divisions of the colon, and that this outlined the haustral divisions much more clearly than would the solution originally injected. This was illustrated by him at that time.

Holzknecht and Brauner, 1906, used a watery suspension of bismuth subnitrate in the preliminary part of the fluoroscopic study of the stomach (10 gms bismuth subnitrate in 50 gms water, to which is added a tablespoon of milk sugar). Palpation of the stomach in the erect posture made possible the visualization of the mucosal folds. After this procedure, and while the stomach still contained the bismuth suspension, they distended the stomach with gas by having the patient ingest an effervescent mixture of from 4 to 5 gms of tartaric acid and from 5 to 7 gms of sodium bicarbonate. The usual opaque meal consisted of 400 gms of milk gruel and 35 gms of bismuth subnitrate.

Independently, F M Groedel and Erich Meyer, in 1908, recommended the substitution of bismuth subcarbonate for bismuth subnitrate. Due to impurities frequently present in the bismuth subnitrate there was the danger of poisoning from the use of this salt.

The essayist, in 1909, with intent to show the mucosal folds, used the principle of sedimentation of bismuth subnitrate from a watery suspension as a special technic for the demonstration of the mucosal pattern on the anterior and posterior walls of the stomach (Figs 7 and 8).

Bachem and Gunther, 1910, introduced the use of barium sulphate. Cannon used or suggested the use of barium sulphate as early as 1904.

The mixture of opaque salts with gruel formed a stiff meal which did not readily fill the folds of the mucosa of the stomach. For this reason, after about 1908, in the United States, the opaque salts were mixed with buttermilk. This formed a non-sedimenting suspension of fluid consistency.

Stiller, 1910, criticized the use of the bismuth gruel opaque meal, claiming that its use produced an abnormal condition of the stomach due to the high specific gravity of the meal and the astringent influence of bismuth upon the stomach. For several years there was considerable controversy on this subject.

von Elischer, 1911, working to settle this controversy, sought to study the stomach with a contrast substance, of the smallest amount necessary to make

the stomach completely visible, and one which would do away with the high specific gravity and possible chemical irritation of the bismuth meal. He used a thick fluid emulsion mass composed of 75 gms of "Zirkonovyd" and from 30 to 40 c.c. of mucilage of acacia. Of this emulsion, from 30 to 40 c.c., which has a weight of from 50 to 60 gms, was injected into the stomach through a tube. The patient was then placed prone in different positions for from five to ten minutes so as to get an equal distribution on the mucous membrane of the stomach. von Elischer found that the emulsion distributes itself over the entire inner surface and fills the folds of the mucous membrane. He considered that this method showed the shape of a gastric tumor more accurately than the usual opaque meal. He also used inflation of the stomach with air in combination with the contrast emulsion.

Forssell, 1913, states "The relief of the mucous membrane can appear inside of the flatness of the roentgen picture in case a less opaque content is used, or if the content is distributed in a thin layer (von Elischer's method)." Åkerlund, 1921, working in association with Forssell, applied the method of the thin layer to the roentgenologic diagnosis of lesions of the duodenal bulb by using external pressure to displace from the bulb all except a thin layer of the opaque content.

This same method was immediately adopted by Eisler and Lenk, 1921, who used small amounts of barium solution, together with pressure from without, regulated under fluoroscopic control, for the study of the inner surface (mucosal folds) of the stomach.

Baastrup, in a paper read in June, 1923, suggested two methods for obtaining films of the mucous membrane of the stomach. The first method was inflation of the stomach with air saturated with barium powder (similar to a method advanced by Laurell for the examination of the colon). The method was difficult to employ and was soon abandoned. This was similar to the blower demonstrated by Einhorn in 1899. The second method is based upon the physiologic studies of rats' stomachs and the studies on humans of Kaufmann and Kienbock (1911), by which it has been shown that the food latest partaken of gets inside of the food first ingested. "The patient, while still fasting, is given, first, half a tablespoonful of barium sulphate stirred up with water to a smooth, rather thick emulsion, then, shortly afterwards, about seven ounces of smooth rice-flour porridge, of rather thick consistency and flavored with a little powdered cinnamon or sugar, but without any thin fluid."

Rendich, 1923, used a thick emulsion very similar in nature to that previously described by von Elischer. Mucilage of acacia 50 per cent (powdered gum arabic to an equal volume of water) was employed, to which an equal quantity (by volume) of bismuth subcarbonate is added. Honey was also substituted for the mucilage of acacia but did not prove as satisfactory. This emulsion was administered to the patient while he was in the partially recumbent position (10° incline). In this communication Rendich does not

make any mention of the previous work which had been done, particularly of the work of von Elischer, which he practically duplicated, and does not mention that while studying in the Army Training School he became fully conversant with your essayist's method of sedimentation of bismuth from thin watery solutions onto the anterior and posterior walls of the stomach.

Pribram and Kleiber (1927), Hilpert (1928), and Vallebona (1926) have revived the combined use of a barium suspension and air distention. The work of Pribram and Kleiber has been limited to the duodenum, while that of Hilpert and Vallebona has had to do with both the stomach and duodenal bulb. Small amounts of barium suspension are ingested and distributed between the rugæ by manual pressure and then the stomach is distended by air injected through a small tube (Pribram and Kleiber, Hilpert), or by chemical means (Vallebona). This method has the disadvantage of diminishing the prominence of the mucosal relief by the distention of the stomach and duodenum.

Trautner and Hoecker, 1927, introduced into the stomach a tube, the end of which was covered with a thin rubber bladder. The bladder was moderately distended with air, and then a small barium meal was given which would settle between the bladder and the gastric wall.

Certain phases of the work of three observers, Åkerlund, Berg, and Chaoul, demand special attention. Åkerlund and Berg use, as a contrast mixture, barium and water in the proportion of three parts of barium to four parts of water. Chaoul uses a mixture of barium, tragacanth, and water. With all three of these observers the element of pressure is the main part of the procedure in securing the distribution of the opaque medium and in acquiring the optimal demonstration of the mucosal pattern.

Åkerlund originally maintained that the method of applying pressure should be as simple as possible. He used the Forssell fluoroscope, designed for both fluoroscopy and roentgenography. The screen of this fluoroscope is so arranged that it may be pressed against the patient and locked in position with the maintenance of any desired degree of pressure. For localized pressure, Åkerlund inserted between the screen and the patient pads of hard cotton, wool, cork or other non-opaque material. Subsequently, he has developed two other methods of pressure. The first is a cone which may be attached to the back of the fluoroscopic screen, into the end of which cone is mounted an inflatable rubber bag. The finer degrees of pressure are obtained by inflation of this rubber bag. The second method is a larger tube to which has been adapted a skillfully designed carrier containing a rotary Bucky diaphragm, and cassette holder. The desired amount of pressure is first secured by fluoroscopic observation, and then the carrier of the Potter-Bucky grid and cassette is substituted for the fluoroscopic screen. The carrier must be withdrawn and reloaded for each exposure, which renders rapid, frequent exposures impossible.

Berg also uses a fluoroscope designed for both fluoroscopy and roentgen-

ography Pressure is obtained by a tube mounted on the back of the fluoroscopic screen His apparatus is so arranged that at the moment he sees a fluoroscopic image which he wishes to record, almost instantaneously a cassette is dropped into place, the transformer setting is changed for roentgenography, and the exposure is completed

Chaoul exerts pressure through a rubber bag strapped in position by means of a leather belt and under fluoroscopic control Serial roentgenograms are made with the patient in the prone position on a roentgenographic and indirect fluoroscopic table similar to the Cole table Chaoul uses the fluoroscope only for localization and for the control of the pressure exerted by the inflated rubber bag

Colon—The universal method for roentgenographic examination of the colon has been to fill the colon completely with an opaque clyster This was originally used by Rieder (1904) With some modifications in the composition of the opaque solution this method has remained the routine procedure Laurell (1921) and A W Fischer (1923) suggested the combined use of an opaque suspension and air injection Laurell injected the colon with air while it was filled with a barium meal Fischer administered a barium enema, then had the patient evacuate the enema, after which a small amount of the opaque suspension remained in the colon He would then inject air into the colon Some of the opaque suspension would remain as a coating on the wall of the colon and its shadow would be sharply defined from the shadow of the air distending the colon This procedure, of course, would show the mucosal surface with the lumen of the colon distended and, therefore, with a minimum folding of the mucosa

The more common procedure has been to study the colon after evacuation of the opaque enema, at which time the mucosal folds are most prominent, due to contraction of the colon, and are well outlined by the thin layer of opaque mixture which remains in the contracted areas of the colon after evacuation This method has been used extensively by Knothe, Berg, Fischer, and Pansdorf, as well as by Frick, Bluhbaum, and Kalkbrenner, and has been routinely used by your essayist since 1915

In the following sections we present a resumé of our own technical methods and certain principles of procedure which have been found helpful These are discussed under four headings

- (1) Apparatus—Technic of Serial Roentgenography
- (2) Preparation of the Patient.
- (3) Choice and Administration of the Opaque Medium, and Roentgenographic Projection and Posture of the Patient
- (4) Application of the X-rays

(1) APPARATUS—TECHNIC OF SERIAL ROENTGENOGRAPHY

Considering the numerous exposures which are necessary for serial roentgenography, it is essential for economic reasons that the roentgenograms

should be as small as is practical to show the region being examined. Extremely small films of the cap and valve are not satisfactory except as complementary evidence used in conjunction with larger films of the entire stomach. To show the entire stomach we have used as small as $6\frac{1}{2} \times 8\frac{1}{2}$ films but prefer 8×10 films for this purpose. We prefer single films for each exposure, rather than multiple exposures on a large film. Multiple exposures on large films are used by some roentgenologists to simplify developing. When this is done the large film should be cut later into single exposures so that the roentgenograms may be matched over each other.

In order to use small films some sort of apparatus which enables one to center the stomach under fluoroscopic control is essential. The reflecting fluoroscope with the mirror set at a 45-degree angle is the best and safest device, especially for the prone posture. The 45-degree angle of the mirror is very essential. Our gradual development of this apparatus in the early days of gastro-intestinal roentgenography and the fact that in some simple form at least it was available in all the institutions with which I was associated, prevented me from recognizing how difficult it was to practise serial roentgenography without such an apparatus. However, when my office was burned in 1924, we were compelled to practise serial roentgenography for a time without such an apparatus, and for the first time I appreciated the difficulties of those who attempt to do serial roentgenography without a convenient method for centering the stomach and changing the films or cassettes.

Why manufacturers are unwilling to build the simple device which we have employed for so many years without making some change of their own that renders it impractical, and why roentgenologists shy from the application of the 45-degree mirror visualization of the fluoroscopic screen with some simple film-changing device, and why they attempt numerous complicated impractical substitutes similar to that recently described by Grier at the meeting of the American Roentgen Ray Society, is one of the mental quirks that it is difficult for me to understand.

The serial table which we use in my private office (Fig. 9) was built as an emergency table just after the fire in 1924 and we have used it ever since. It is so simple that it may be built by any carpenter and, therefore, it does not elicit the interest of the manufacturers of X-ray equipment. It is a box 40 inches high, 36 inches wide, and 7 feet long, placed against a partition which may be a permanent wall or a portable partition which separates the table from an operating booth. Figure 10 shows the details of construction.

Any standard cassettes may be used in a lighted booth. Only one set of screens is necessary if the booth is dark, otherwise, 6 or 8 cassettes with 12 or 16 screens are necessary. The same principle is used for the erect position, with the patient standing at the foot of the table.

A more elaborate serial table has been designed and constructed by one of us (C. I. H.) that may be used without a booth, but it requires cassettes unless it is operated in a darkened room (Fig. 11).

A very simple device consisting of a box about 20 by 24 inches and 10 inches deep, with one side open and a bakelite panel in the top, with a mirror to reflect the image of the fluoroscopic screen, and a horizontal shelf to apply the cassettes to the under surface of the patient, is the simplest of all (Fig 12) With a wooden leaf at each end which folds back on the top, this box can be placed on any table, and when not in use the leaf at each end folds back on the top of the box and it may be placed on the floor and used as a convenient stool or step This device was first used at General Hospital No 1 and was dubbed the "Baby Grand "

The value of serial films is very greatly diminished unless one has illuminating facilities so that all the films can be observed and studied at once, and, therefore, an illuminating box 40 inches high and at least 8 feet long is essential

A much more elaborate roentgenocinematographic apparatus has been installed in the Joseph Purcell Memorial Laboratory at the Fifth Avenue Hospital, through the generosity of his wife, Anna Purcell True moving pictures of the stomach and intestine may be made with this apparatus on a roll film 10 inches wide This film is perforated at the edge and may be moved 10 inches between each exposure By use of a gear shift, similar in size and construction to an automobile gear shift, several different speeds may be used Exposures may be made at the rate of 4 per second, 3 per second, 2 per second, 1 per second, or 1 every two seconds, or single exposures at any time interval desired This apparatus may be used either in the horizontal position for the prone or supine postures, or in the vertical position for the erect posture It is shown in Figures 13 and 14 The large film may be reduced to the standard 31 mm (Fig 15) or the sub-standard 16 mm film and projected either from a standard or sub-standard motion picture projector, showing not only the motion of the stomach but that of the small intestine, and the relation of rapidity of motion of one to the other [This film was demonstrated at the Third International Congress of Radiology in Paris, July, 1931]

(2) PREPARATION OF THE PATIENT

For an examination of the esophagus, stomach, and small intestine, the patient should be in an over-night fasting condition, without catharsis Even with this precaution and in cases without obstruction, small amounts of food residue are not infrequently found to be present in the stomach In such cases a longer period of starvation may be necessary After gastric lavage or after expulsion of the test meal, small quantities of the lavage fluid and of the test meal remain in the stomach and blur the outline of the barium shadow This is particularly important in the study of the surface of the mucosa by the "thin layer technic" Food remnants, mucus, and air bubbles all produce a confusing mottling of the shadow which may completely destroy

all the finer detail. For an examination of the colon or small intestine by colon enema, the patient should have a thorough catharsis, preferably by castor oil (from 1 to 2 ounces). The cathartic should be given twenty-four hours before the examination is to be made. Waiting twenty-four hours after the giving of the cathartic allows the spastic effect of the cathartic to subside and does away with troublesome spasm during the giving of the enema. Fasting is not essential.

In the colon, as in the stomach, the presence of food remnants (feces) produces a mottling of the contrast shadow which destroys the fine detail and often simulates in appearance certain pathologic findings. We do not believe that the colon can be satisfactorily evacuated by the aid of cleansing enemas. Not only does this method fail to evacuate all of the fecal material, but there is, also, a retention of part of the cleansing solution—which is just as disturbing as the original contents of the colon.

(3) CHOICE AND ADMINISTRATION OF THE OPAQUE MEDIUM AND ROENTGENOGRAPHIC PROJECTION AND POSTURE OF THE PATIENT

As the opaque substance we use, routinely, chemically pure barium sulphate for examination of all parts of the gastro-intestinal tract. We use the single opaque meal, following the progress of this meal through the entire gastro-intestinal tract. This serves to establish the emptying time of the stomach, identifies all parts of the intestinal tract, and indicates the progress of the ingested meal through the small intestine and colon. *If there is any suspicion of an obstructive lesion in the colon, the study of the colon by means of the barium enema should precede the barium meal.*

Esophagus—For an examination of the esophagus we use a thick paste of barium and water, so thick that the patient cannot swallow it without mixing it with saliva. This thick paste will pass down the esophagus slowly and some of it will remain in the esophagus for a considerable period of time, even with the patient erect. Fluoroscopic and roentgenographic examination may be made in either the erect or supine posture. For the usual roentgenographic examination and to obtain a greater filling of the esophagus it is best to administer the paste to the patient while he is in the horizontal position. For a study of the peristalsis in the esophagus Palugyay elevates the pelvis above the level of the shoulders so that the opaque paste must be forced up an inclined plane.

The esophagus must be studied in the antero-posterior and both oblique projections, exactly as one would step around a tree in order to study its outline.

The demonstration of the mucosal surface by a thin layer depends upon the retention of the opaque substance between the folds of the mucosa or its adherence to the surface of the mucosa. This is difficult to control. We believe this can be best accomplished by originally giving a very small amount

A very simple device consisting of a box about 20 by 24 inches and 10 inches deep, with one side open and a bakelite panel in the top, with a mirror to reflect the image of the fluoroscopic screen, and a horizontal shelf to apply the cassettes to the under surface of the patient, is the simplest of all (Fig 12) With a wooden leaf at each end which folds back on the top, this box can be placed on any table, and when not in use the leaf at each end folds back on the top of the box and it may be placed on the floor and used as a convenient stool or step This device was first used at General Hospital No 1 and was dubbed the "Baby Grand "

The value of serial films is very greatly diminished unless one has illuminating facilities so that all the films can be observed and studied at once, and, therefore, an illuminating box 40 inches high and at least 8 feet long is essential

A much more elaborate roentgenocinematographic apparatus has been installed in the Joseph Purcell Memorial Laboratory at the Fifth Avenue Hospital, through the generosity of his wife, Anna Purcell True moving pictures of the stomach and intestine may be made with this apparatus on a roll film 10 inches wide This film is perforated at the edge and may be moved 10 inches between each exposure By use of a gear shift, similar in size and construction to an automobile gear shift, several different speeds may be used Exposures may be made at the rate of 4 per second, 3 per second, 2 per second, 1 per second, or 1 every two seconds, or single exposures at any time interval desired This apparatus may be used either in the horizontal position for the prone or supine postures, or in the vertical position for the erect posture It is shown in Figures 13 and 14 The large film may be reduced to the standard 31 mm (Fig 15) or the sub-standard 16 mm film and projected either from a standard or sub-standard motion picture projector, showing not only the motion of the stomach but that of the small intestine, and the relation of rapidity of motion of one to the other [This film was demonstrated at the Third International Congress of Radiology in Paris, July, 1931]

(2) PREPARATION OF THE PATIENT

For an examination of the esophagus, stomach, and small intestine, the patient should be in an over-night fasting condition, without catharsis Even with this precaution and in cases without obstruction, small amounts of food residue are not infrequently found to be present in the stomach In such cases a longer period of starvation may be necessary After gastric lavage or after expulsion of the test meal, small quantities of the lavage fluid and of the test meal remain in the stomach and blur the outline of the barium shadow This is particularly important in the study of the surface of the mucosa by the "thin layer technic" Food remnants, mucus, and air bubbles all produce a confusing mottling of the shadow which may completely destroy

Examinations are made routinely at one-half, two, four, and six hours after ingestion of the barium meal, but may be made at more frequent intervals if necessary

It is *absolutely* essential, if one is to obtain the best roentgenograms of the small intestine, that there be no nutrient value in the menstruum in which the barium is suspended. This eliminates buttermilk, malted milk, and, also, flavoring extracts. Sustained fasting is essential.

Roentgenographic examination of the small intestine is made only with the patient in the prone position. Comparative roentgenograms were made in both the prone and erect postures and it has been found that (1) The position of the small intestine varied but little in the two postures, (2) the loops of the small intestine were more discretely shown in the prone position, (3) there was no appreciable distortion of the small intestine in the prone position.

It must be remembered, however, that the preceding remarks regarding the position in which the small intestine is studied apply to the use of the barium meal. When one is examining the abdomen to determine whether or not there is an abnormal dilatation of any of the loops of the small intestine by gas due to obstruction, the erect posture is very helpful, in that it allows one to visualize fluid levels in the gas-filled intestine.

Pansdorf varies this procedure slightly in that he does not give the barium meal at one time, but in fractions, the patient taking one swallow every ten or fifteen minutes. This diminishes the bulk of the opaque mixture in the intestinal coils and does not serve as well to demonstrate their caliber.

The colon as outlined by the barium meal is examined daily, the roentgenograms revealing the progress of the barium meal through this region.

Visualization of the Mucosal Pattern of the Stomach—The visualization of the mucosal pattern depends fundamentally upon a satisfactory distribution of an opaque suspension in the furrows between the mucosal folds. There are two methods (1) The use of a moderate amount of a thin suspension of an opaque salt, through which can be seen the shadow due to displacement of the opaque suspension by the folds of the mucosa, and (2) the methods of the "thin layer".

In roentgenograms made with the first method the folds are shown as less opaque linear shadows within the flat whiteness of the gastric shadow. This method has the disadvantage that the shadow of the opaque suspension as a whole lacks sharpness because of the small content of opaque material.

The method of the "thin layer" may be applied in several ways. The bulk of a full or small sized barium meal may, by external pressure, be displaced from a local region of the stomach or cap, leaving only a thin layer which does not conceal the shadows of the thicker layers of opaque substance which are present in the furrows between the mucosal folds.

The more common and satisfactory procedure is to give only a small amount of the barium-and-water mixture (8.5), a sufficient amount to fill

—a level teaspoonful—of the thick paste. This will usually be sufficient to leave a thin coating of barium on and between the folds of the mucosa.

The Barium Meal.—The contour of the stomach, we find, is best shown after a full barium meal—8 oz by weight of barium to 5 oz of water—is administered. This amount—7-oz volume—is less than that employed by most observers but is all that is necessary. Over-distention of the stomach is undesirable as it not only gives a less satisfactory visualization of the stomach and cap, but, also, causes the stomach to obscure an unnecessary amount of upper intestine. This amount of barium insures that the margin of the gastric shadow will be very sharp.

To establish the contours of the various surfaces of the stomach, roentgenograms should be made in the postero-anterior projection and both the right and left oblique projections. For the right, or first, oblique projection, the right side of the patient is against the film, for the left, or second oblique projection, the left side of the patient is against the film.

Roentgenograms made in the postero-anterior projection should be made with the patient both erect and prone, as the profile of the postero-anterior projection is not the same in the erect and prone postures.

The oblique projections may be made with the patient either erect or prone. We believe that the erect posture is preferable, as the anterior and posterior surfaces of the stomach are brought more into profile with the patient erect. In the prone-oblique posture there is a rotation and a lateral shift in position of the stomach.

The roentgenographic examination of the stomach in the erect position should be made as soon after ingestion of the barium meal as the cap and duodenum begin to fill. One of the chief sources of failure to obtain good roentgenograms in the erect posture is that the making of the roentgenograms is delayed by fluoroscopic examination until the gastric muscle has lost its tone and is unable to hold the barium in a column. Early lack of tone and peristalsis may be stimulated by external irritation, either a slap with the hand or a dash of cold water.

When an individual assumes the supine position most of the gastric contents flow back into the fornix of the stomach. This position is very useful when one wishes to study the upper part of the stomach in a dilated state.

The Small Intestine.—The same moderately thick mixture of barium sulphate and water (8 5) serves as the best medium for a roentgenographic visualization of the small intestine. The following conditions must be fulfilled to secure roentgenographic visualization of the small intestine:

- 1 The opaque medium must be of such composition and consistency that it will pass out of the stomach at a fairly rapid and uniform rate of speed.
- 2 The medium must be of sufficient consistency to pass evenly—and, preferably, very slowly—through the small intestine.
- 3 Roentgenographic examinations must be made at intervals which will show the various parts of the small intestines when they are best filled.

The Barium Clyster—The solution which we use is a suspension of barium sulphate in mucilage of acacia and water 10 ounces by weight of barium sulphate, 7 ounces of mucilage of acacia, and 32 ounces of water. This solution should be warmed to body temperature before injection. The injection is made by gravity through a rubber enema tube to the end of which is attached a funnel. The rapidity and pressure of the injection is controlled by the height of the funnel above the patient's body. The use of the funnel allows one to see at all times whether or not the suspension is going in rapidly, or slowly, or not at all. Back-flow of the suspension into the funnel is due to temporary contraction or spasm of the colon. The suspension should be injected slowly and at a low pressure. If this is done, one rarely fails to fill the normal colon completely. The injection is followed under fluoroscopic control and should be stopped as soon as the cecum is filled. Over-distention of the colon is a disadvantage.

When the colon is completely filled, a roentgenogram is made with the patient in the prone position, the ray being projected in the postero-anterior direction. As in other parts of the intestinal tract, we are dealing with a tube which must be viewed from several angles to bring its several contours into profile. This is particularly true of the colon because of the usual overlapping of the transverse colon and the ascending and descending colon at the hepatic and splenic flexures, respectively. Therefore, roentgenograms should be made in both the right and left prone-oblique positions, with sufficient rotation of the patient's body to make visible, in turn, these two flexures of the colon. This procedure is an excellent protection against the very real possibility of overlooking a lesion due to overlapping of the different parts of the colon.

After these roentgenograms have been made, the colon should be evacuated, either by the patient or by drainage through the enema tube. The study of the colon after evacuation is just as important as the study of the filled colon. It is essential to know whether or not there is an unusual retention of any division of the colon, particularly proximal to the hepatic flexure. In addition, a thin layer of the barium mixture remains on the mucosa of the colon and gives an excellent demonstration of the mucosal pattern of the contracted colon. The studies by Knothe, Berg, and Frick, Bluhbaum and Kalkbrenner of the mucosa of the colon have all utilized this slight retention of the opaque mixture after evacuation.

A W Fischer (1923) recommends the combined use of an opaque mixture and air injection. He uses the usual opaque mixture. After evacuation, he studies the mucosal pattern of the contracted colon, and then injects air into the colon. A thin layer of opaque mixture adheres to the surface of the mucosa and when the colon is distended with air, one obtains, at times, an excellent visualization of the mucosal surface. The results are difficult to control and duplicate.

the furrows but not enough to cover the folds. If too little of the barium mixture is used, some of the furrows may not be filled. If too much is employed, the mountain peaks of the mucosal folds may be so flooded by the mixture as to be completely obscured in the roentgenogram.

The greatest difficulty with this method is to secure a satisfactory distribution of the small amount of barium mixture in the stomach. Special methods for the distribution of the barium have been devised to show the rugae most clearly and to emphasize the mucosal pattern.

When a small amount of the barium mixture is administered, it passes along the lesser curvature in such a manner that this region has been termed the gastric pathway, and trickles into the by-ways of the crinkled rugae along the greater curvature. Eventually the remainder of the paste is deposited in the antrum; some, perhaps, passes into the cap. This method of distribution depends upon the normal gastric motor phenomenon. Most observers have the patient assume various postures so that the mixture may flow into the furrows with the aid of gravity. Some observers, with more or less success, have attempted to assist Nature by spreading or smearing the barium paste over the surface of the mucosa by using deep manual massage of the abdominal wall, either with or without fluoroscopic control.

Distribution of the Opaque Salt by Sedimentation.—This method was originally employed by the author when he attempted to develop the special mucosal technic previously mentioned. This is accomplished by administering through a drinking tube to a patient in the prone posture, on a flat table, about 1 gram of bismuth subnitrate or bismuth subcarbonate in 4 oz of water. This amount of solution moderately distends the stomach. In from fifteen to twenty minutes the bismuth settles or gravitates onto the furrows between the mucosal folds of the anterior gastric wall. If the correct amount of bismuth has been used, it just fills the furrows between the rugae and the results illustrated in Figures 7 and 8 are obtained. If too large an amount of bismuth is used in 4 oz of water, the furrows are more than filled and the mucosal folds are covered, so that the results are unsatisfactory. A modification of this method is to fill the stomach more completely with a watery solution of 1 gram of bismuth to 8 oz (120 c.c.) of water. With this larger amount of water, the mucosal folds are smoothed out so that the bismuth settles onto a relatively smooth surface. Then, as the water is drawn off by means of a small tube, the stomach diminishes in size, the mucosa is thrown into folds, and the bismuth becomes incarcerated within the furrows between the folds. We have found that the sedimentation of the bismuth is accelerated if the required amount of dry bismuth is placed on the tongue and then washed down with the 4 or 8 oz of water.

A preliminary washing out of the stomach with an alkaline solution, in order to dissolve the mucus, makes this method even more satisfactory. The mucosa of the posterior gastric wall may be likewise demonstrated by placing the patient in the supine posture.

secondary rays His device employs compression in the following manner Between the fluoroscope or film and the patient he causes pressure to be exerted on the abdomen, which is soft and compressible, rather than on the patient's back, where the ribs and spine render it practically incompressible This procedure is not new To it, however, Åkerlund added a revolving grid located in the end of the cylinder that is pressed against the patient For the perfection of this he deserves great credit By the use of this apparatus, one diminishes the detrimental effects of the secondary rays that are generated in a relatively large region However, the revolving grid that increases the brilliancy of the roentgenogram, as does any other grid, likewise adds to the time of exposure and likewise adds the disagreeable grid characteristics, while its large size prevents local application of pressure Some of the prominent observers who previously used this apparatus, realizing that the smaller the area of observation, the less valuable the grid, discontinued its use This method, although employing two of the five methods of diminishing the detrimental effects of secondary radiation, namely, compression and the grid, does not utilize the other three, that is, the tube, the cone, and the close apposition of the film to the opaque medium

Berg employs a method similar to Åkerlund's, but without the revolving grid Of the five methods of diminishing the detrimental effects of secondary rays, Berg depends chiefly on compression applied to the abdomen by a cylinder or cone mounted on the back of the fluoroscopic screen In doing this he has exaggerated *reversely* the fifth principle by placing the film away from the patient Berg, with this apparatus under fluoroscopic control, is able to exert any desired pressure on the stomach or cap, displacing the bulk of the barium mixture and leaving only that which is caught in the furrows between the mucosal folds He is enabled thus to make a thorough fluoroscopic exploration of the gastric mucosa When any interesting area is observed fluoroscopically a film is substituted for the screen and a radiographic record is made In this procedure only one method of obviating the detrimental effects of secondary rays is employed, namely, compression By this method Berg gets a gross elimination of the widely scattered secondary rays, and he speaks of the Bucky effect of the cylinder A close scrutiny of the illustrations appearing in Berg's book indicates that his most brilliant roentgenographs are those in which his special compression apparatus has not been used

It should be noted that in both Åkerlund's and Berg's compression cylinders the fluoroscopic screen or film is inserted at the end of the cylinder and is at a very considerable distance from the patient, therefore, the screen and film are not in close apposition to the region being examined In Åkerlund's device the film is separated from the patient by the thickness of the grid and the housing over the grid The fifth principle—close apposition of the fluoroscopic screen or film to the part being examined—which is perhaps the most important of the five principles for eliminating secondary radiation, is em-

(+) APPLICATION OF THE X-RAYS

Roentgenograms may include an entire region, such as stomach, cap, and duodenum, or they may be limited to small localized areas three or four inches in diameter. Films of an entire region may be made with or without a grid. Those made with a grid are more brilliant, but because of the increased length of time required for exposure, and other unsatisfactory grid characteristics, they are less diagnostic than the roentgenograms made without the grid and with the use of a cone of just sufficient size to include the stomach, cap, and duodenum. A thorough consideration of this subject would in itself require a book. We shall, therefore, mention only the salient principles.

Secondary radiation is the bane of the roentgenologist's existence—particularly true in regard to the gastro-intestinal tract. Five factors have been employed to prevent the development of secondary rays or to obviate their detrimental effect: (1) The gas tube, (2) the cone, (3) compression, (4) the grid, and (5) the close apposition of the film to the opaque medium.

The gas tube generates fewer secondary rays per cubic space radiated than any other tube because of the fact that the indirect rays generated in the gas tube are of very low penetration and are easily eliminated by the cone.

The cone is one of the oldest and is perhaps the most important device for obviating secondary radiation. It utilizes the principle of diminishing the surface area of the region that is being exposed. The smaller the cone, the smaller the surface area (or cubic space) radiated, consequently, the less the secondary radiation, the more brilliant the roentgenogram.

Compression is used to diminish the thickness of the part being exposed. When combined with the cone it diminishes to a minimum size the cubic space exposed to the X-ray. The smaller the cubic space radiated, the less is the secondary radiation. Compression also diminishes the time required for exposure. Compression may be applied either between the tube and the patient's back, or to the patient's abdomen, as will be described later.

The grid tends to eliminate secondary radiation. The larger the area that is exposed to radiation, the more valuable is the grid. Conversely, the smaller the area, the less valuable is the grid. The grid has its advantages and its disadvantages. It increases the time of the exposure twofold or threefold, thus allowing the motion due to peristalsis to become a detrimental factor. It increases also the distance of the film from the patient, causing distortion.

Close apposition of the film to the region under observation not only lessens the amount of secondary radiation, but is an application of the following law of optics, "the nearer an object is to a screen or film, the clearer and more distinct is its shadow."

One or more of these principles to minimize the effect of secondary radiation are applied by the various observers, especially by those who have constructed their own apparatus. The ingenious apparatus designed by Åkerlund utilizes two of these five principles for obviating the detrimental effects of

roentgenographed. By using this apparatus only a very small area is exposed and so the grid would be of little or no value, and actually detrimental.

The fifth principle, that is, close apposition of the film or screen to the part being examined, is employed, bringing about not only a diminution of the secondary rays generated between the stomach and the film, but also a more brilliant and clear-cut image in accordance with the optical law, "the nearer the film to the object, the sharper the shadow."

Pressure.—As regards the roentgenological examination of the gastro-intestinal tract, compression and pressure are entirely different, at least, we shall so regard them. Compression is applied to diminish the thickness of the part and so reduce its secondary rays. Pressure is employed to displace the bulk of the opaque medium (barium) from the lumen of the gut and to accentuate the mucosal pattern. Pressure is usually applied to small areas as by Åkerlund and Berg, although Chaoul applies pressure to larger areas by means of a large, inflatable, flat rubber bag which is strapped to the abdomen. We use both, as is shown in our illustrations. Pressure as applied by Åkerlund and by Berg is usually under fluoroscopic control, that is, the operator personally views the region fluoroscopically. When he sees some finding which is of interest he substitutes a film for the screen and makes a small roentgenograph for a permanent record. While he is making this roentgenograph he can personally orient himself and determine the exact region that is being examined. However, if the small films, especially those of the stomach, were to be observed without a knowledge of the exact region in which they were made, as observed fluoroscopically, it would be difficult to identify the region.

Pressure gives a different set of findings for a criterion on which to base radiographic diagnosis, and undoubtedly it allows a more comprehensive study of the mucosal folds and the surface of the mucosa. In our own experience and by an intensive study of the illustrations submitted by others, we find that there are very few instances in which the diagnosis of an organic lesion has been established by pressure in cases in which it has not been established by radiographs made without pressure.

The manner in which the rugae of the stomach diverge as they approach certain types of carcinomatous growths or the manner in which they converge toward the crater of an ulcer at a certain late stage in its process of repair, are findings of scientific interest. They do not, however, alter the diagnosis as established by the routine method without pressure. It must be remembered that visualization of rugae and application of pressure are not synonymous. Indeed, it is often more difficult to determine the size and shape of the crater of an ulcer when the barium is displaced by pressure than it is when the crater is filled by moderate distention of the stomach without pressure.

External pressure.—whether achieved with Åkerlund's rotary grid, the cylinder used by Berg, a rubber bag strapped to the abdomen as recommended by Chaoul, or with our own apparatus constructed by Headland—has both

ployed by neither Skerlund nor Berg, and the detrimental effects are exaggerated by both of their methods.

Bearing in mind the five factors enumerated as aids to the diminution of the detrimental effects of secondary radiation, one of us (C I H), at the essayist's suggestion, has designed and constructed a device for examining fluoroscopically and roentgenographically small localized areas of the gastrointestinal tract, particularly the stomach and cap (Figs. 16 and 17). The principles employed in this apparatus are as follows:

(1) An X-ray tube is used that generates fewer secondary rays in the patient than any other tube, namely, the gas tube.

(2) A cone is used which has the smallest diameter that will cover a $3\frac{1}{4} \times 4$ inch film at a 24-inch distance.

(3) Compression is exerted on the soft, compressible abdomen by a rectangular piston which has rounded corners. No compression is exerted by the small cone attached to the tube holder.

(4) No grid is used.

(5) The device is so arranged that the intensifying screens and fluoroscopic screen are located at the end of the piston which is pressed into the abdomen. Thus, with pressure, the film and screens are embedded well within the normal contour of the abdomen and in close contact to the opaque medium.

With this device we not only see the exact image which we desire to radiograph prior to the rapid insertion of the film, but we also see the actual fluoroscopic image recorded on the film.

An old-fashioned gas tube is employed because this is the only tube in which indirect rays are not generated on the back of the target. The elimination of indirect rays from the back of the target diminishes the quantity and penetration of the secondary rays generated in the patient. The gas tube is the only tube used for roentgenographic work in the institutions with which I am associated, except in connection with portable and dental apparatus.

The second principle involved in our device for eliminating secondary radiation is the limitation to a minimum size of the surface area exposed to the rays. This principle is accomplished by employing the oldest of all methods for obviating secondary radiation, namely, a cone of such small diameter that it barely covers a $3\frac{1}{4} \times 4$ inch film at a 24-inch distance.

The third principle, namely compression, is applied to the soft parts of the abdomen which are compressible, and in this manner the distance between the film and the posterior surface of the patient is reduced to a minimum. Secondary rays are developed in proportion to the cubic space that is radiated; therefore with a cone of minimum size and with the desired maximum amount of compression, the cubic space radiated is reduced to a minimum. Thus the quantity of secondary rays generated is reduced to a minimum.

The fourth principle, namely the grid, is not used because, as we have stated previously, the grid is chiefly of value when large areas are to be

its advantages and disadvantages as a method of showing or exaggerating the pattern of the mucosal folds. It is a moot question whether or not it should be used. Some observers depend very largely on gradation or dosage of external pressure to displace the bulk of a small opaque meal from a local region so that the mucosal pattern of local regions may be observed fluoroscopically or roentgenographically. Small roentgenographs made with various devices show more contrast than roentgenographs of full size, but with the grid interposed or with the film at the end of the cylinder away from the patient, detail is diminished and distortion results. Even when one is able to obtain small roentgenographs with great brilliancy and without loss of detail there is still much question in my mind as to whether the findings aid or hinder in the diagnosis of gastro-intestinal lesions. Although numerous articles have been illustrated by brilliant, localized roentgenographs, very few observers have recorded any systematic comparison of these small local films obtained by pressure, with routine roentgenographic examinations, serial or otherwise.

We have run quite a large series of cases, making twelve small roentgenographs of the cap with varying degrees of pressure (Figs. 18 and 19), in addition to the routine serial roentgenographic examination. By comparing the findings of the cap, as observed by both methods, we have come to the following conclusions:

Whereas small roentgenographs are much more economical, they are limited to a small region and difficult to orient, except in the cap. The small films of the stomach are almost valueless inasmuch as they cannot be oriented except by comparison with a large film which shows nearly as much detail. The small films furnish brilliant contrasts and are fascinatingly interesting to study, especially with the old-fashioned hand stereoscope to which these $3\frac{1}{4} \times 4$ inch films are so well adapted. Nevertheless, we have yet to find a case in which the small films, made with varying degrees of pressure, have caused us to alter the diagnosis as based on serial films of full size made without pressure. Pressure interferes, in many instances, with the manner in which a normal or pathological cap behaves when it receives a squirt of barium through the pyloric valve, or when its distal two-thirds are evacuated by a broad peristaltic wave. A cap under abnormal external pressure does not act normally in response to the gastric motor phenomenon. Thus external pressure employed to exaggerate the mucosal pattern becomes a two-edged sword with which, I fear, many will cut their fingers!

(To be continued)

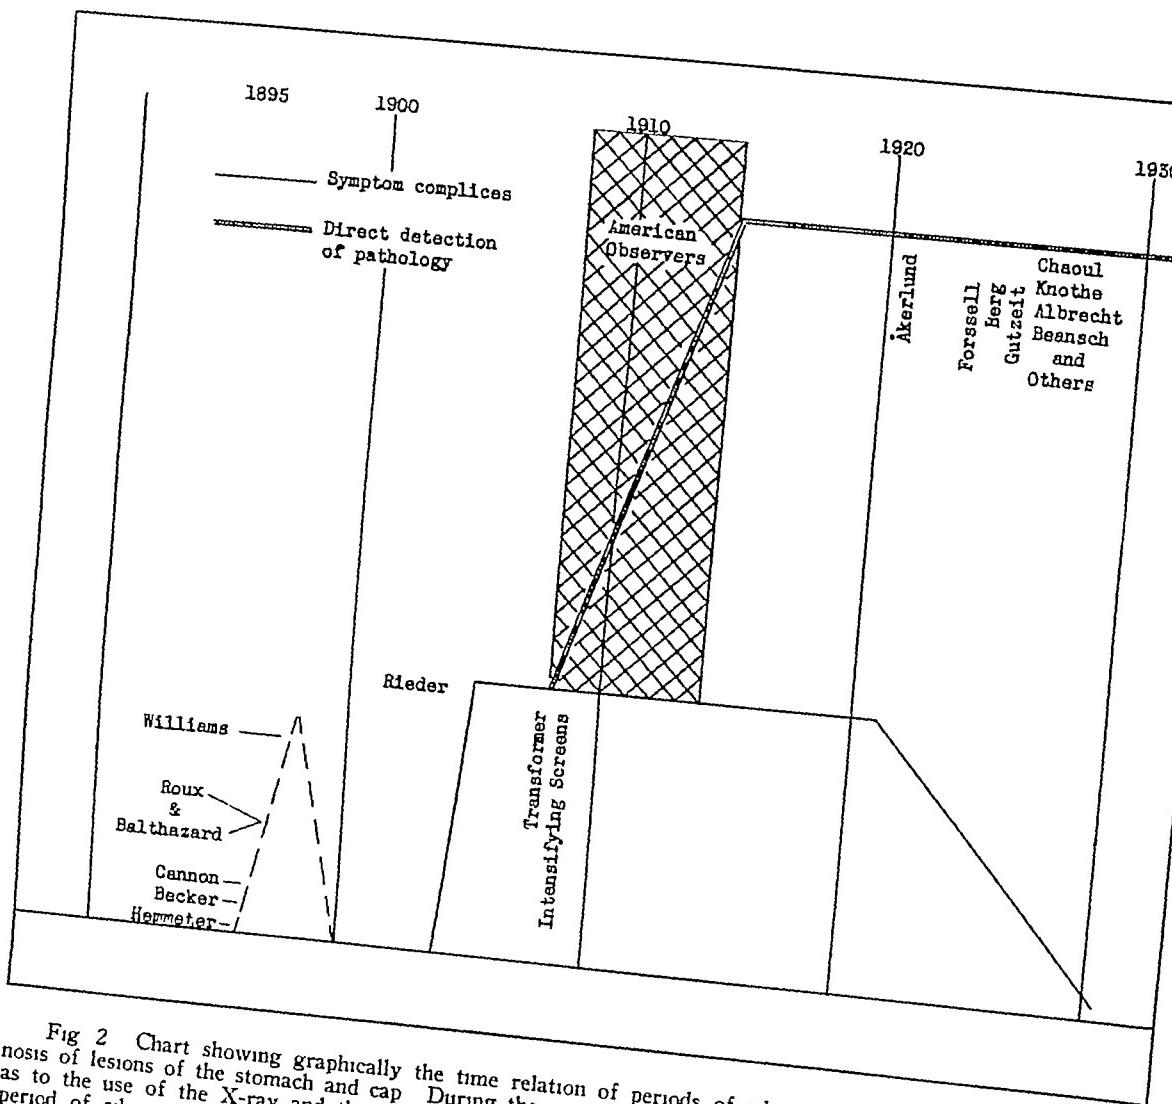

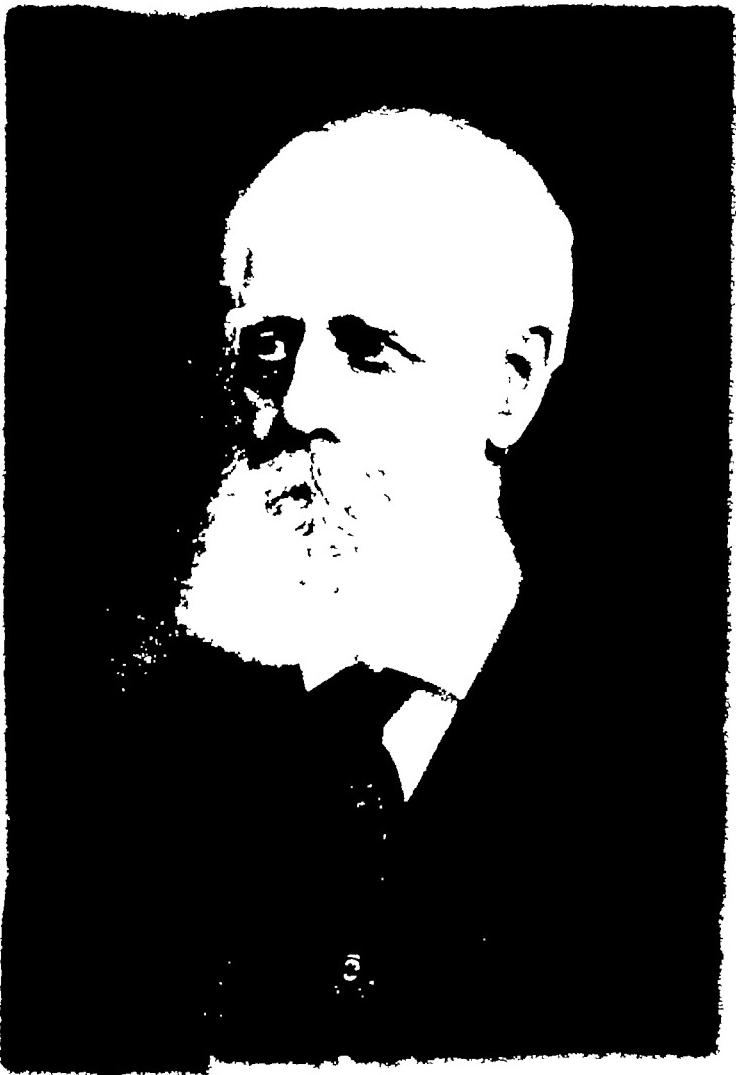

Fig 2 Chart showing graphically the time relation of periods of advance in the roentgenological diagnosis of lesions of the stomach and cap. During the period between 1896 and 1900 observations were made as to the use of the X-ray and the opaque meal for making visible the stomach. From 1900 to 1904 was a period of silence. Rieder's work in 1904 resurrected the use of the X-rays for study of the gastro-intestinal tract, and for the first time roentgenologic examination was used for diagnosis, the criterion for diagnosis of pathologic lesions being the so-called "symptom complices". Satisfactory roentgenography of the stomach was possible only after the introduction of the transformer and intensifying screens in 1908. Roentgenographic examination of the stomach made possible the direct detection of abnormal morphologic changes in the wall of the gut. The period from 1908 to 1914, indicated by the cross-hatched area on the chart, was the "red letter days" of roentgenographic exploration of the gastro-intestinal tract.

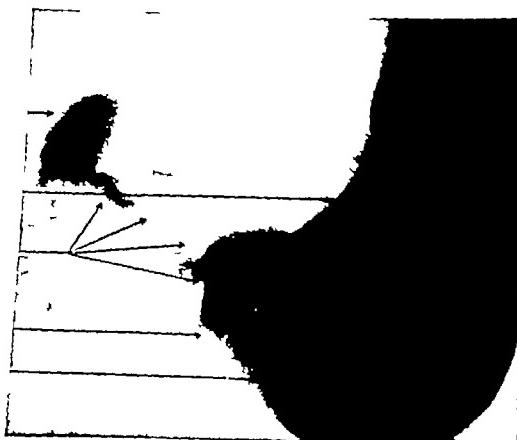

Fig 4' Cancer of the stomach.

The changes shown in the above roentgenograms were designated as filling defects, due either to spasm as shown in Figures 3 and 3 prime, where the rugæ are observed more distinctly than usual, or to a cancer protruding into the lumen of the stomach as shown in Figures 4 and 4 prime where the rugæ in the involved area are completely obliterated. These figures illustrated an article originally published in 1912, and these reproductions are made from the same photo-engraved blocks.

Fig 7 Patient, Mr S, Oct 13, 1910 This roentgenogram was the essayist's first intentional attempt to demonstrate the pattern of the gastric mucosa by a special technic. The patient ingested a suspension of one gram of bismuth subnitrate in four ounces of water, and was placed in the prone posture for twenty minutes, the heavy bismuth settling out of suspension onto the mucosal folds of the stomach

Fig 6 Roentgenograms showing the passage of the barium meal through the small and large intestine, and examination of the colon after administration of the opaque enema and after its evacuation indicate, together with Figure 5, what the essayist originally designated as serial roentgenography of the gastro-intestinal tract

Fig 7 Patient, Mr S, Oct 13, 1910 This roentgenogram was the essayist's first intentional attempt to demonstrate the pattern of the gastric mucosa by a special technic. The patient ingested a suspension of one gram of bismuth subnitrate in four ounces of water, and was placed in the prone posture for twenty minutes, the heavy bismuth settling out of suspension onto the furrows between the mucosal folds of the stomach

Fig 8 Serial roentgenography, *i.e.*, multiple roentgenograms of the stomach in combination with the special mucosal technic as illustrated in Figure 7, shows the constancy of position of the mucosal folds except as they are disturbed by the progressive peristaltic contractions

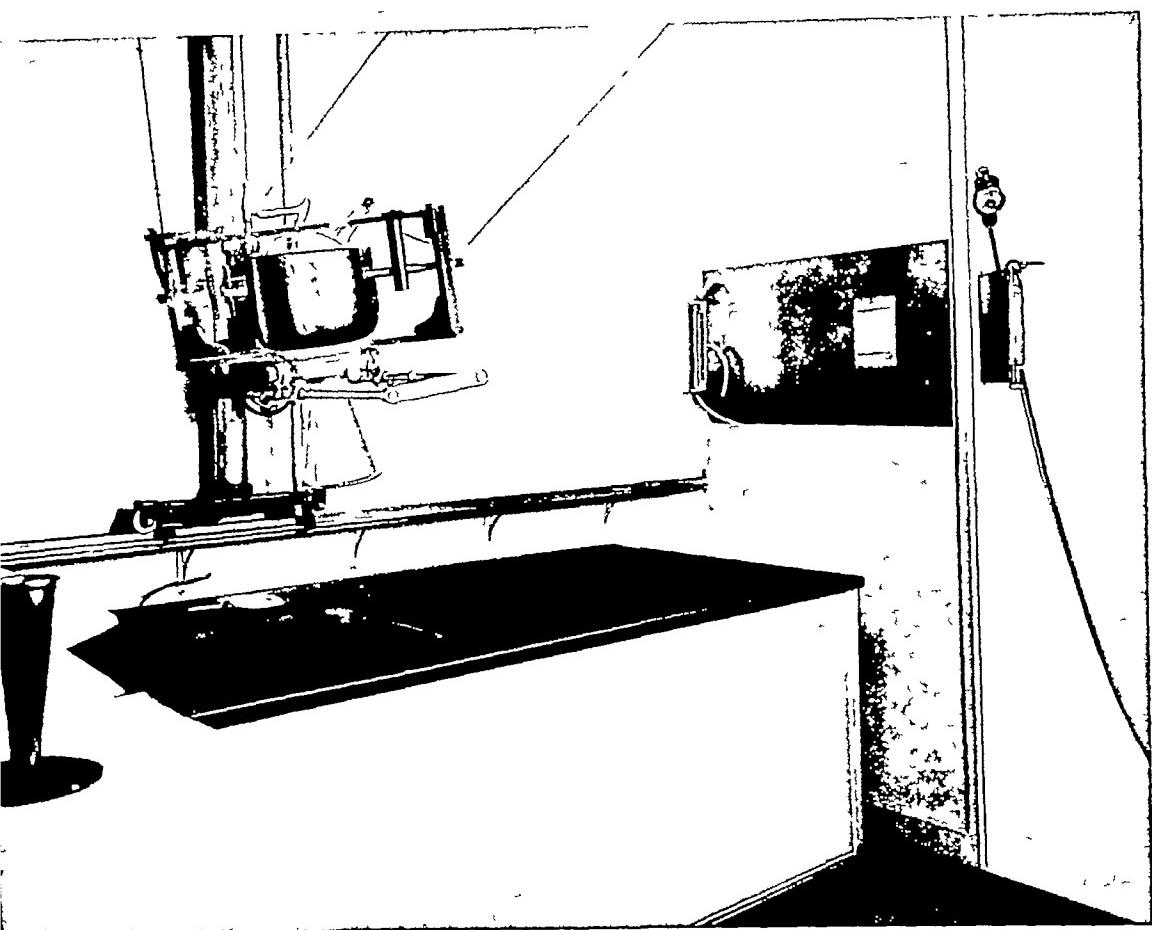

Fig 9 Serial table, built as an emergency table just after the fire in 1924, since which time it has been in constant use. This table is a box 40 inches high, 36 inches wide, and 7 feet long, built into a wall concealing a dark operating booth. The bakelite panel in the top of the table is the top of the film-changing device shown in detail in the cross-sectional drawing (Figure 10).

The bakelite panel in the wall at the end of the table conceals the film-changing apparatus for making serial roentgenograms of the patient in the erect posture. This film-changing apparatus is a cassette built into the wall, entirely similar to the erect film-changing apparatus shown in the Model Table designed and constructed by Headland (Figure 10). The back of the cassette is made of bakelite, and carries the back intensifying screen in front and a fluoroscopic screen behind. The fluoroscopic screen is covered with lead glass. The patient is held tightly in position by the belt shown in the picture. The holders of the belt are offset from the wall so that the angle of the belt is not acute and will not slip easily. The holder on the right side, which contains the ratchet gear, is mounted on hinges, so that it may be swung back out of the way into the position shown in the photograph.

The compression device designed and constructed by Headland can be seen partially protruding through the bakelite panel in the end wall. The detailed construction of this is shown in Figures 16 and 17. The small cone on the table in the foreground is used when we make the small compression roentgenograms and will just cover a $3\frac{1}{4} \times 4$ inch film at a 24-inch distance.

The small rubber bag shown lying on the table behind the bakelite panel may be attached to a rubber tube for use with either the prone or erect apparatus. It is used for exerting pressure on relatively large areas of the stomach and colon, and is inflated from the operating booth under fluoroscopic control.

Exposures may be made either from the operating booth or from the room itself, in the latter case by using the hand switch hanging on the wall.

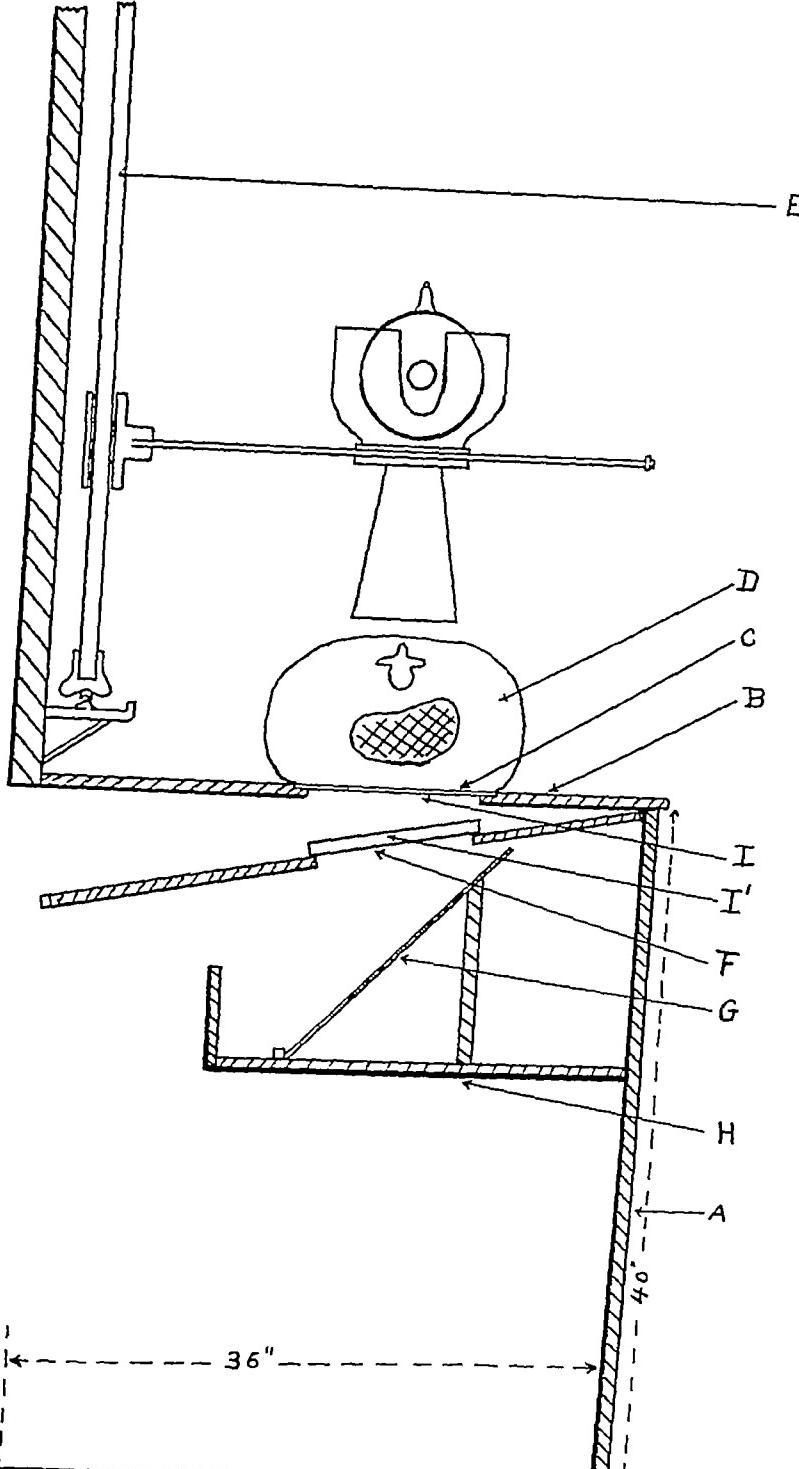

Fig 10 Cross-sectional drawing of the serial table shown in Figure 9. *A*, a wooden box 40 inches high, 36 inches wide, and 7 feet long *B*, wooden top of box *C*, bakelite panel mounted in the top surface of the box *D*, cross-section of patient in the prone posture. *E*, tube stand mounted on rail on the side wall. This mounting of the tube stand is optional, as one may also use a floor tube stand *F*, fluoroscopic screen, surface down *G*, mirror in which to view the fluoroscopic screen *H*, lead-lined box to prevent secondary rays from hitting operator *I*, intensifying screen, surface down. *I'*, intensifying screen surface up *I* and *I'* are for use with naked films when the booth is dark. Any standard cassette may be used in a lighted booth. Only one set of screens is necessary if the booth is dark, otherwise 6 or 8 cassettes with 12 or 16 screens are necessary. The same principle is used for the erect position, with the patient standing at the foot of the table.

The entire table and the exposed wall of the booth is lined with lead, which is indicated by the heavy black line in the drawing

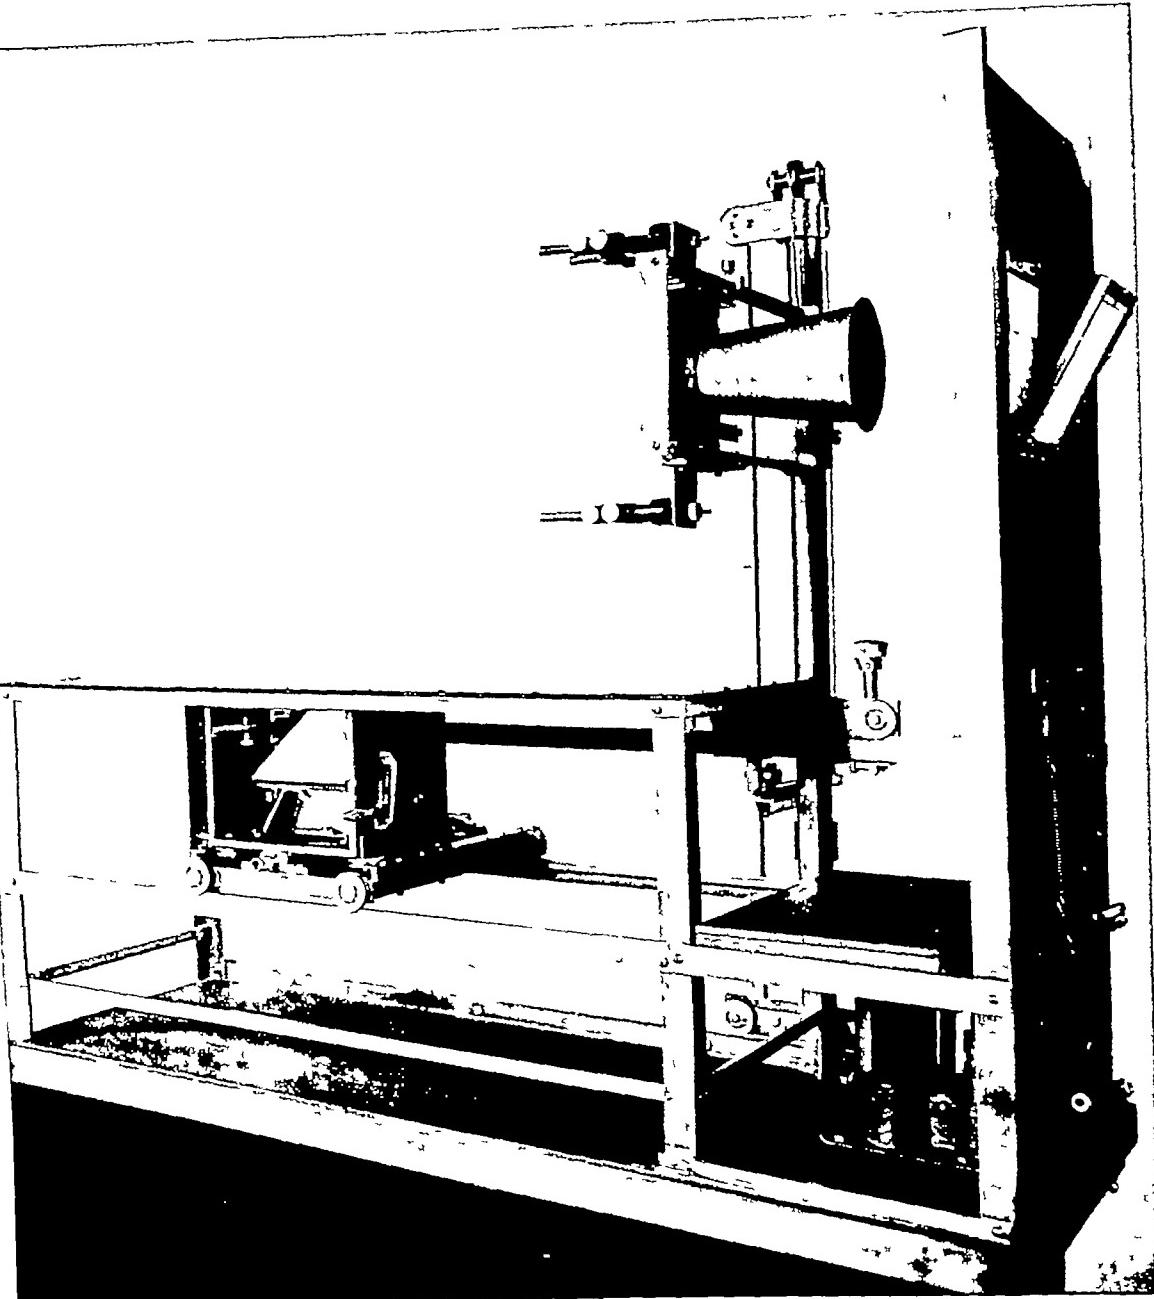

Fig 11. Model of serial table designed and constructed by C I Headland, M.D. This table may be used as it is in a darkened room, or may be mounted as an integral part of the wall of an operator's dark room

In the prone film-changing apparatus the movable hinged shelf which carries above, the lower intensifying screen, and, below, the fluoroscopic screen, is shown hanging down so that the intensifying screen is visible. Below this is the 45-degree angle mirror, and in the mirror one can see the reflected image of the fluoroscopic screen. This box may be interlocked with the tube stand so that the cone automatically is centered to the intensifying and fluoroscopic screens, when the apparatus is moved either up and down or across the table. Thus, by moving the tube stand and film-changing apparatus as a unit, one can localize and center the stomach without moving the patient.

For roentgenography in the erect posture the patient stands upon the platform at the end of the table, facing the lead-lined vertical panel. The platform is mounted on an hydraulic elevator, and the lowering and raising of the elevator is controlled by the two levers which pass through the vertical panel. The film-changing apparatus mounted in the vertical panel is a cassette, the back of which has been replaced by a bakelite cover on the front of which is mounted the back intensifying screen, and on the back of which is mounted the fluoroscopic screen covered with lead glass.

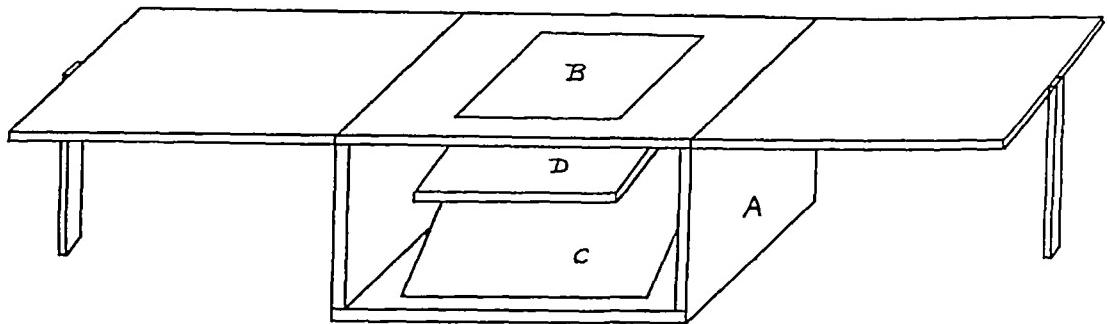

Fig 12 Diagrammatic drawing of the simplest type of apparatus for serial roentgenography. This was primarily constructed and actually used at Base Hospital No 1 4, a flat wooden box *B*, a bakelite panel mounted in the top of the box *C*, a mirror, set at an angle of 45 degrees, to reflect the fluoroscopic image *D*, a wooden shelf attached by hinges to the back side of the box so that it is movable. A fluoroscopic screen is mounted on the under side of this shelf, the fluorescent surface facing the mirror. Cassettes are slid onto the top of the shelf, so that when the shelf is held up against the top, either by the hand or a locking device, the cassette is pressed firmly against the under surface of the bakelite panel. At both ends of the box are leaves of wood to support the patient's body. These leaves are not quite as long as the box and may be so hinged that when not in use the leaves may be folded back on the top of the box, and the entire apparatus may then be used as a step or stool.

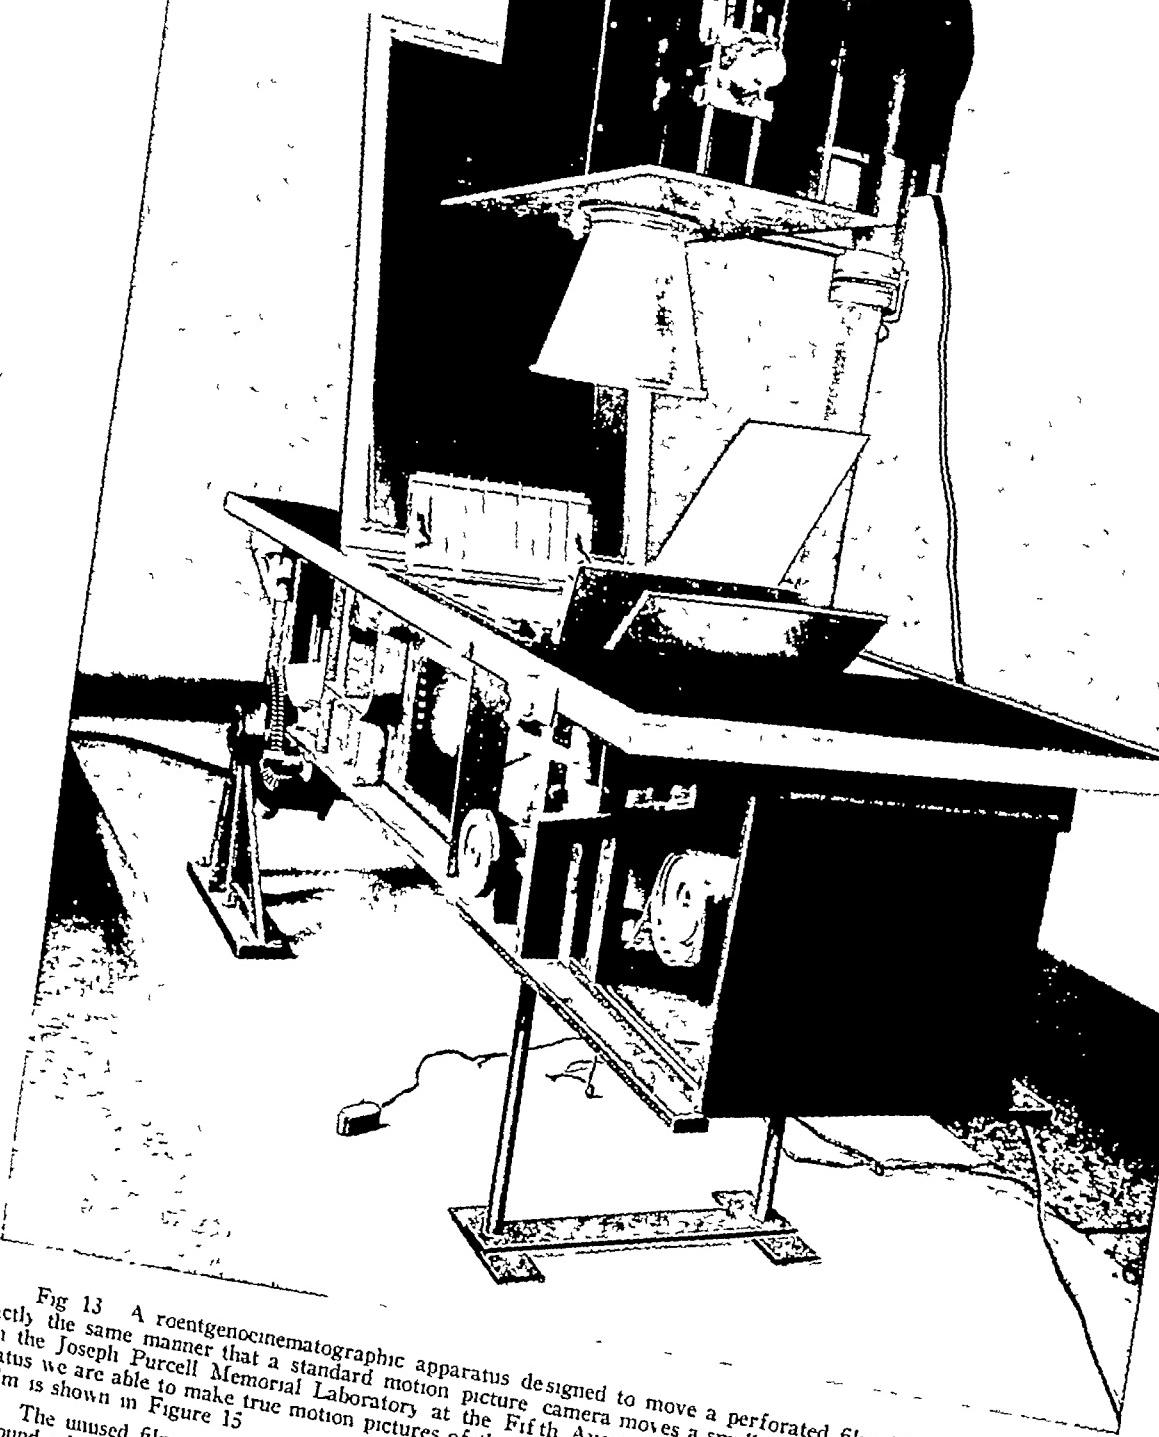

Fig 13. A roentgenocinematographic apparatus designed to move a perforated film 10 inches wide in exactly the same manner that a standard motion picture camera moves a smaller film. This apparatus is installed in the Joseph Purcell Memorial Laboratory at the Fifth Avenue Hospital, New York City. With this apparatus we are able to make true motion pictures of the stomach and a short run of a roentgenocinematographic film is shown in Figure 15.

The unused film is contained in a magazine and is shown under the near end of the table. After passing around wheels with sprockets the film is threaded between intensifying screens and then through rollers back into another magazine at the far end of the table. In this photograph the apparatus is opened up for threading, and when the doors of the apparatus and the table top are closed it appears as is shown in Figure 14. A worm gear at the far end of the table enables it to be used in either the horizontal or vertical position or at any desired angle. The same reflecting mirror which has been employed on the serial tables, enables one to observe the action of the stomach both prior to the making of the film and during the time that the film is actually being exposed.

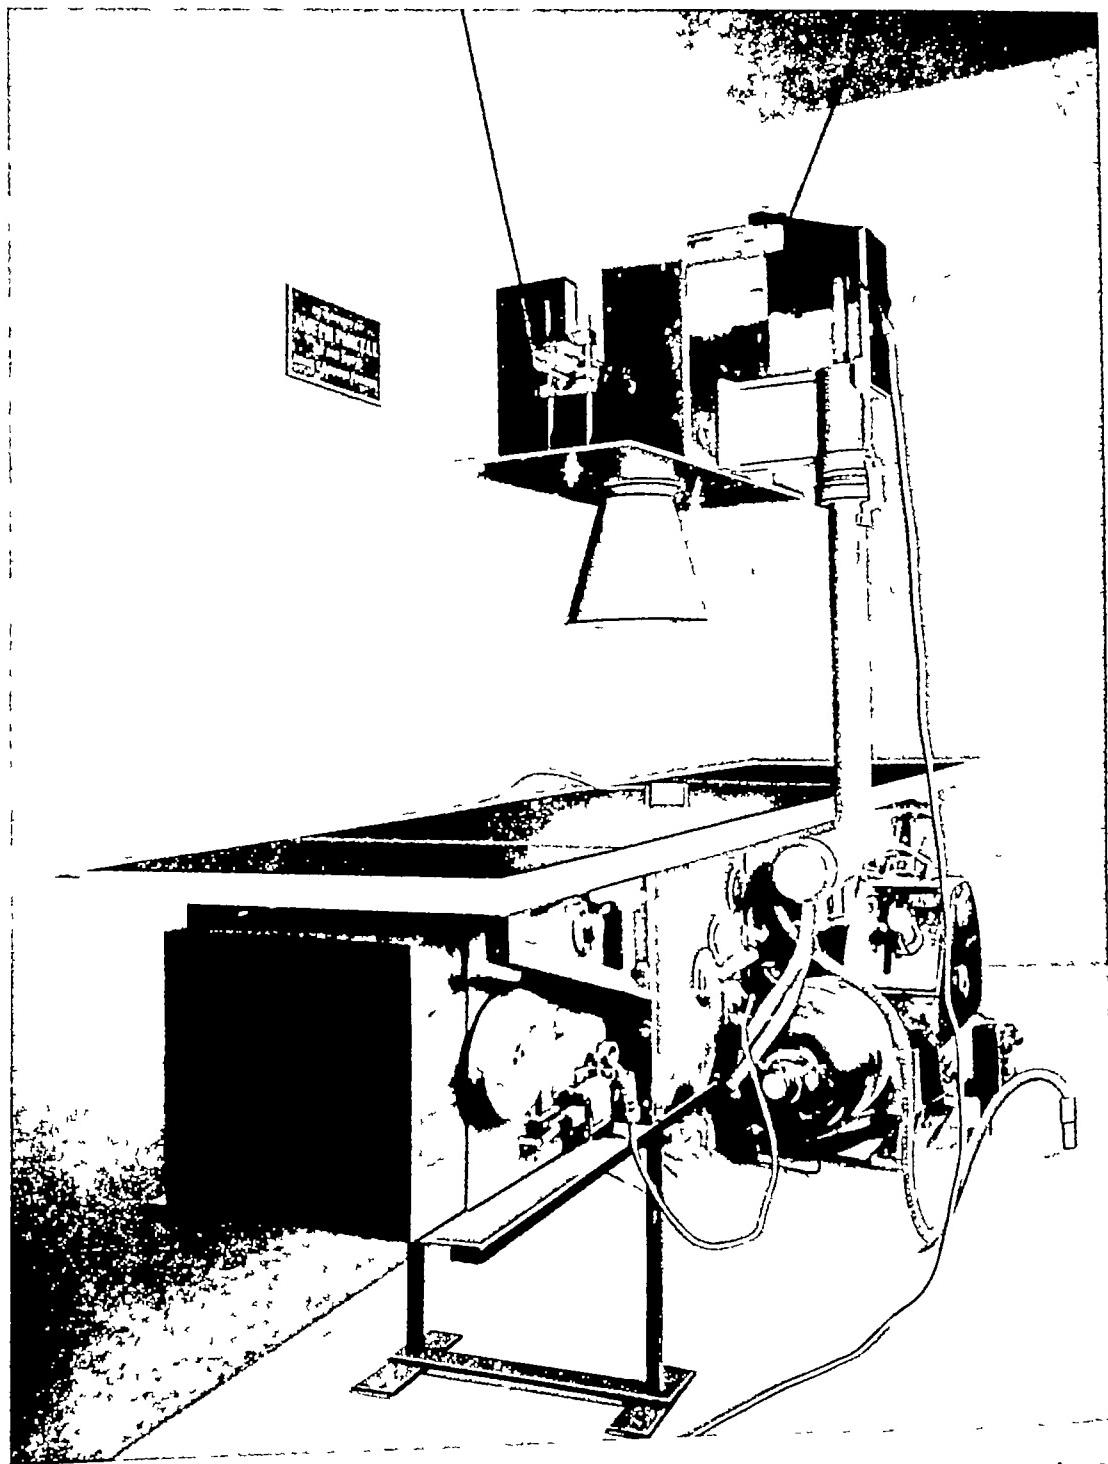

Fig. 14. The roentgenocinematographic apparatus closed and ready for action. The tube is enclosed in a ray-proof box. The timing of the exposures is accomplished by a switch at the top of the tube stand which may be used to break either the secondary or primary current. The motor which drives the mechanical parts is observed in the foreground, and just behind this is a speed-changing device similar in size and shape to a gear shift on an automobile, which enables us to make a continuous roentgenographic film at various rates of speed.

NITRATE FILM
PANCHROMATIC

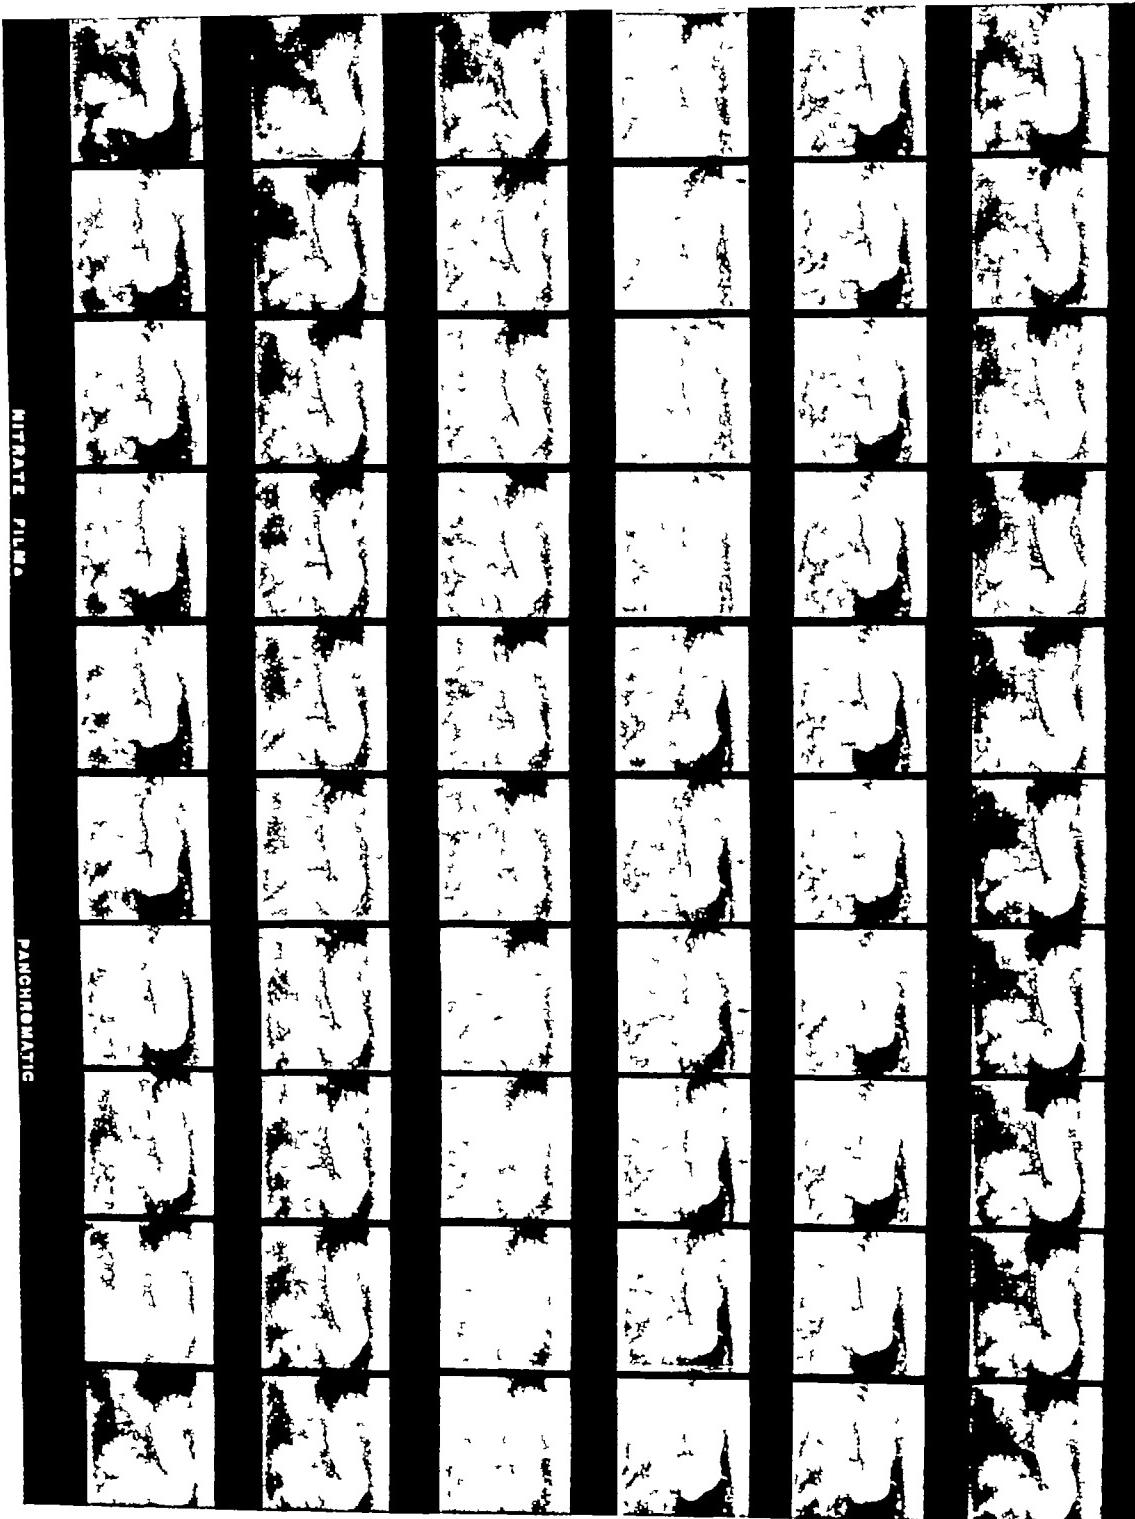

Fig 15 Shows a short run of roentgenocinematographic film of the stomach made with the apparatus illustrated in Figures 13 and 14

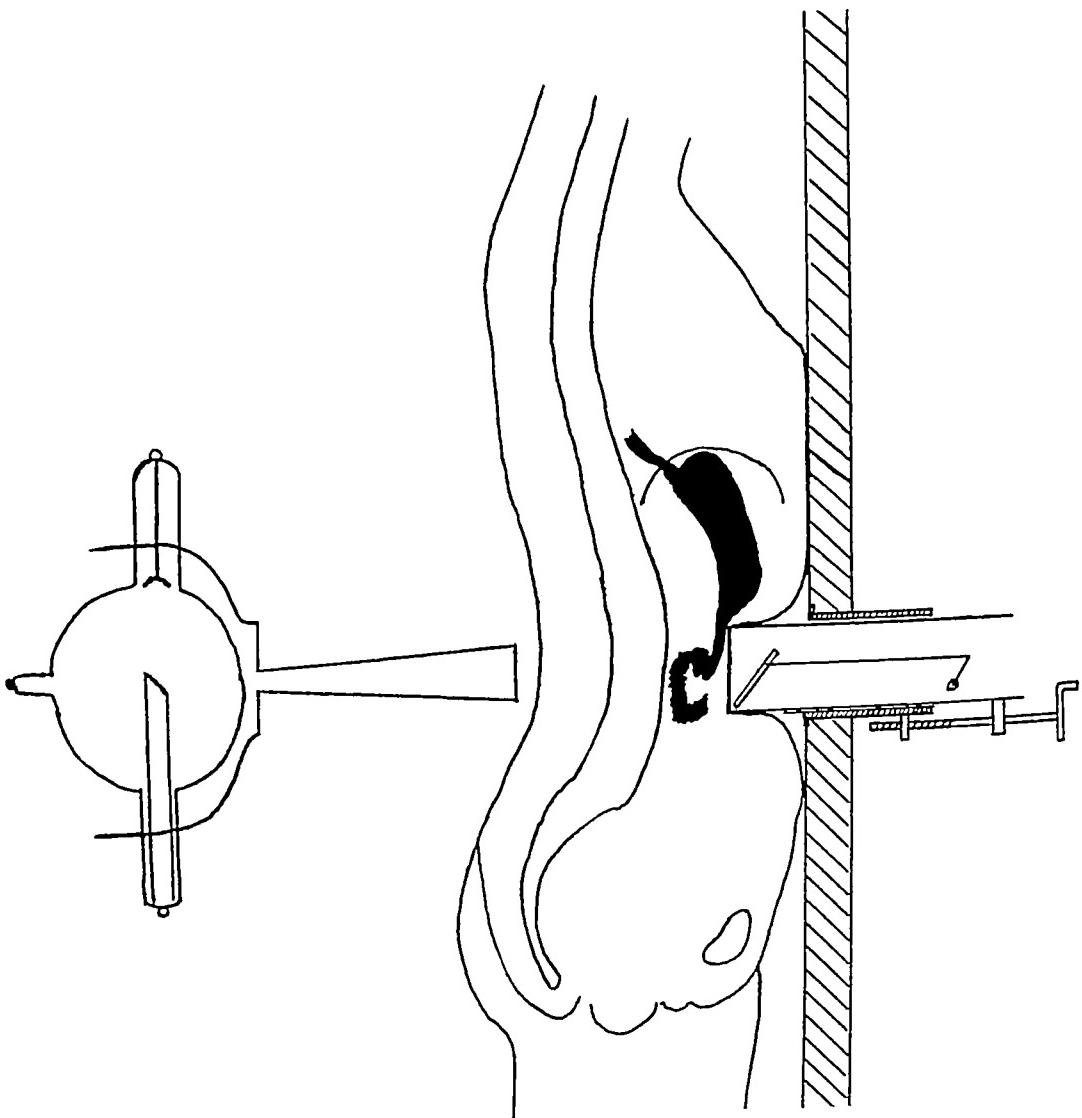

Fig 16 Diagrammatic drawing showing the method of use of the compression apparatus designed and constructed by C I Headland, M D. The patient is held against the face of the wall by the strap shown in Figure 9. This figure also shows the face of the apparatus protruding through the wall.

Compression is exerted on the soft, compressible abdomen by a rectangular piston which has rounded corners and is faced with a beveled layer of cork (third principle). The piston is pressed into the anterior abdominal wall by means of the screw gear. The intensifying screens and the fluoroscopic screen, mounted inside the front of the piston, are thus buried in the anterior abdominal wall and in extremely close contact with the opaque medium (fifth principle). No grid is used, the film being separated from the abdominal wall by only a thin intensifying screen and a thin layer of bakelite and cork. The gas tube is used which generates fewer secondary rays in the patient than any other tube (first principle). A cone is used which has the smallest diameter that will cover a $3\frac{1}{4} \times 4$ inch film at a 24-inch distance (second principle). The region to be examined is localized and the degree of compression desired is obtained under fluoroscopic examination. The image recorded in the roentgenogram is observed fluoroscopically at the instant of exposure.

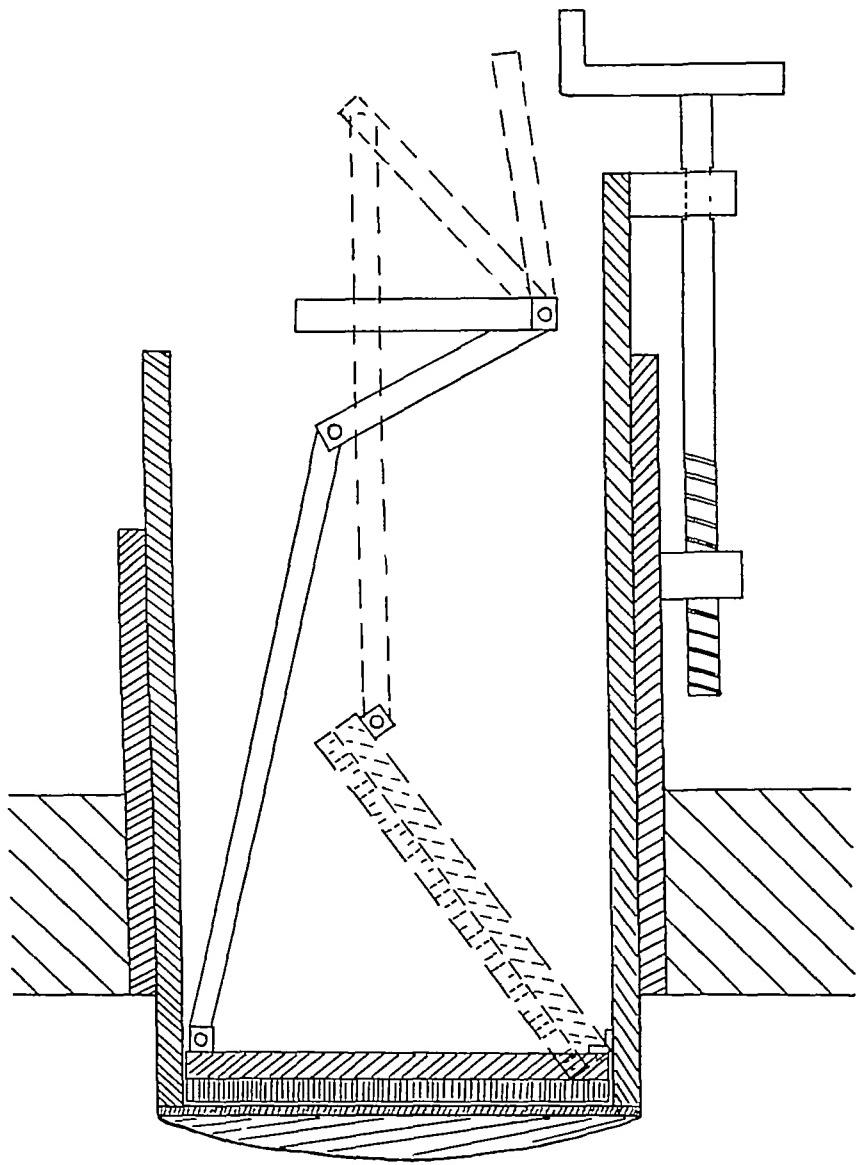

Fig. 17 Diagrammatic cross-sectional drawing showing the plan of construction of the compression device designed by C I Headland, M D. The dotted lines show the position of the movable plate when drawn back for insertion or removal of the film. On this movable plate are mounted the back intensifying screen and the fluoroscopic screen.

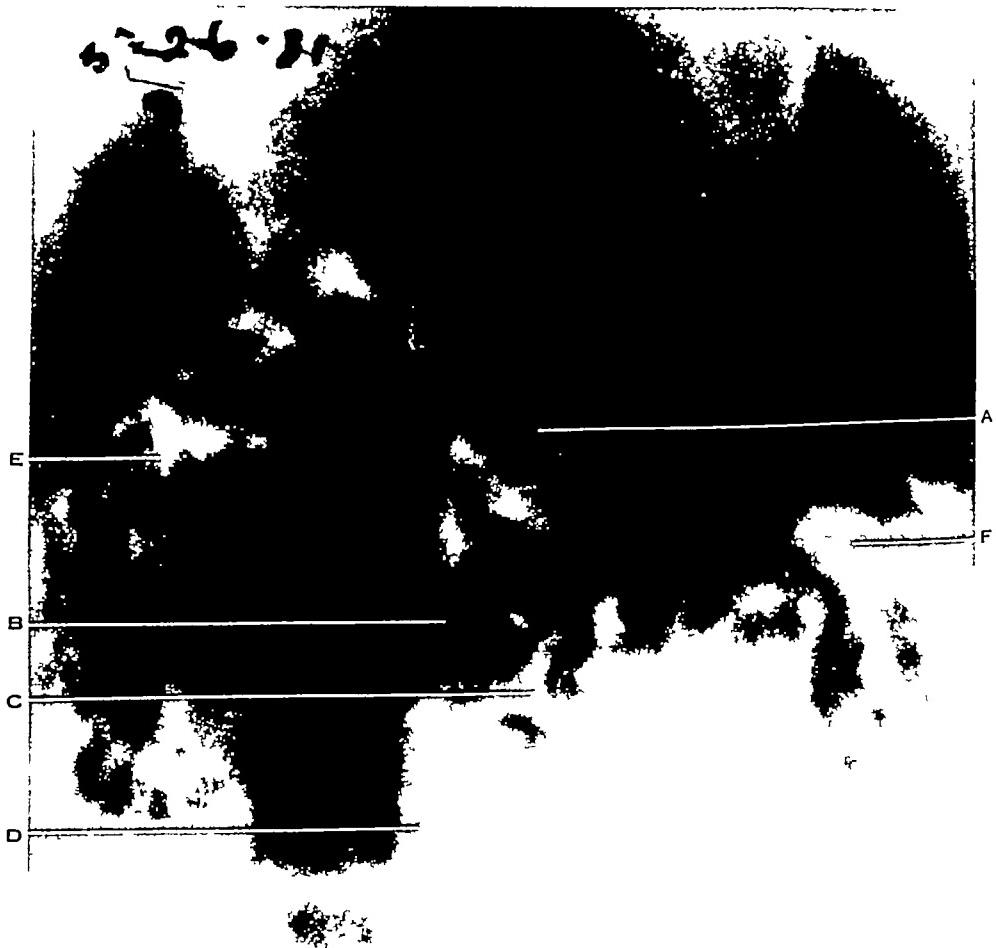

Fig 18 An enlargement of a $3\frac{1}{4} \times 4$ inch film similar to those shown in actual size in Figure 19. This is presented to show the detail and contrast as reproduced on the photo engraving directly from the original film. This detail is obtained by using four out of the five fundamental principles for eliminating secondary radiation described in the text, namely, (1) gas tube, (2) small cone, (3) compression (5) close apposition of the film to the part being examined. The fourth principle, the revolving grid, is not employed.

A, the cap, with criss-cross arrangement of the mucosal folds. B, pyloric valve C, pyloric canal D, antrum E, descending duodenum F, duodenojejunal flexure.

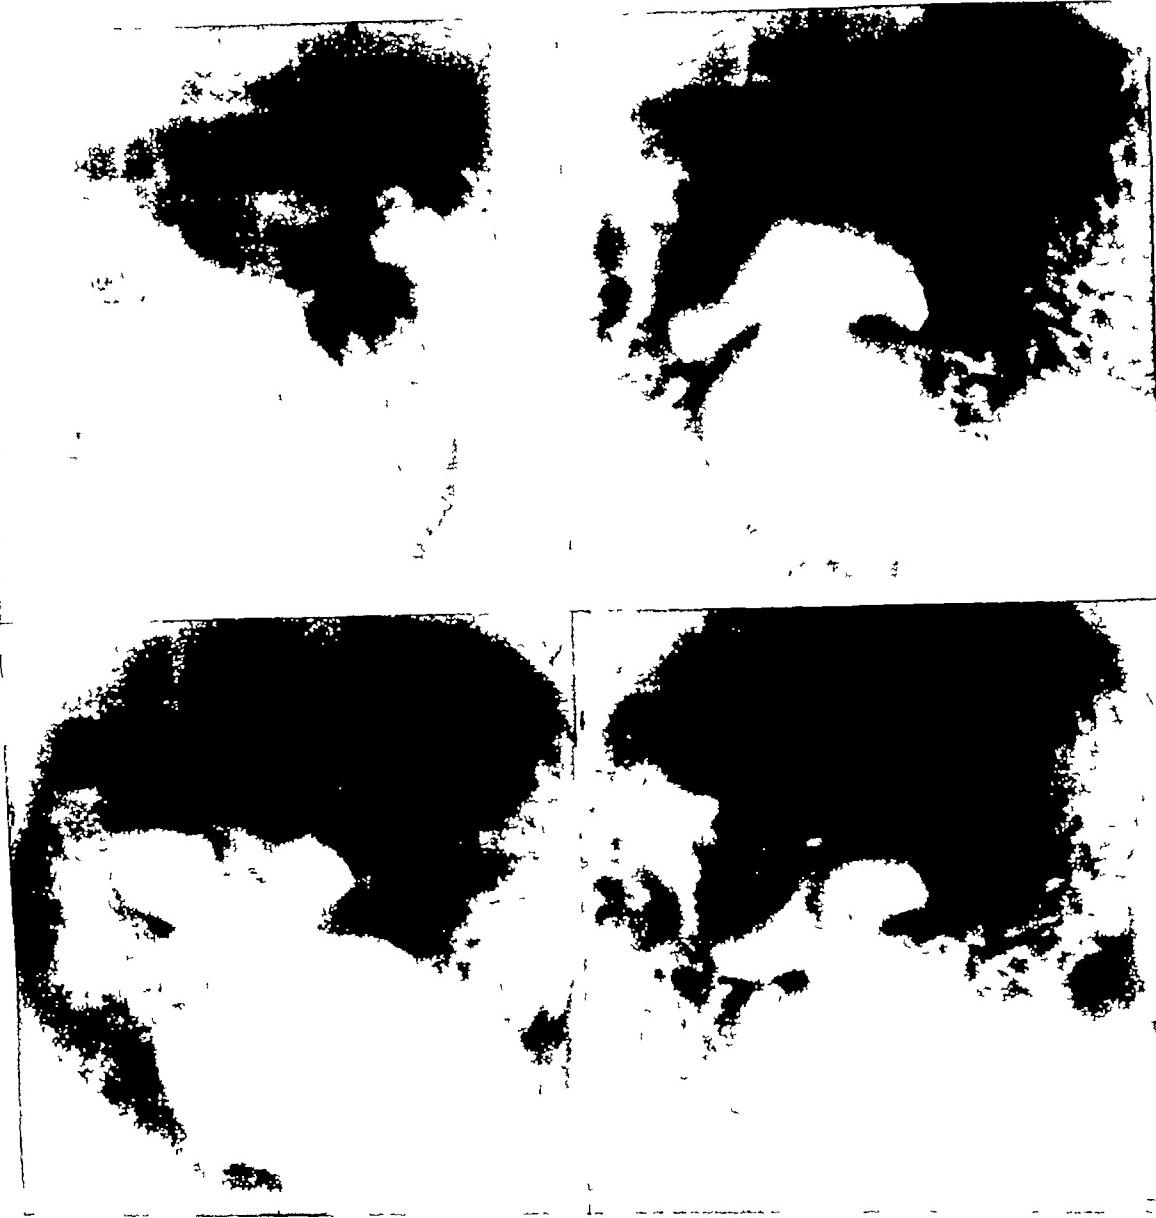

Fig 19 Roentgenograms showing four stages of graduated pressure on the same cap. These are reproduced in actual size directly from the original films. A small ulcer on the posterior surface of the cap is shown distinctly, but it is not as characteristic as the crater deformity shown in the oblique films of the cap without pressure, which will be illustrated later when describing ulcers of the cap.

THE GAMMA RADIATION OF RADIO-ACTIVE SUBSTANCES

By JEAN THIBAUD, D Sc., Director of X-ray Laboratory of School of Higher Studies,
Faculty of Sciences, PARIS

Translation by HENRY BAYON, M.D., New Orleans, La

GAMMA radiation is emitted by a considerable number of radio-active elements which bear a close relationship to X-rays. This very complex radiation constitutes a spectrum of lines, characteristic of the discharging radio-element, the wave lengths of which vary from 0.25 to 0.005 Ångstrom unit. This means that the gamma rays extend the territory of X-rays to high frequencies. Their energies expressed in volts can vary from 50,000 to over two millions.

The power of penetration of these radiations is, in general, far superior to that of

in material substances includes both a classic effect (Thomson) without change of wave length and a Compton effect. The quantum of scattering in this instance assumes an importance which becomes more considerable as the frequency increases, and for radiations, the energy of which corresponds to more than a half-million volts, it is just about the only one observed.

The softest gamma rays exhibit very distinct diffractive effects in crystals, effects which have been utilized in the measurement of their wave length (Rutherford and Andrade, Frille, Thibaud). The author

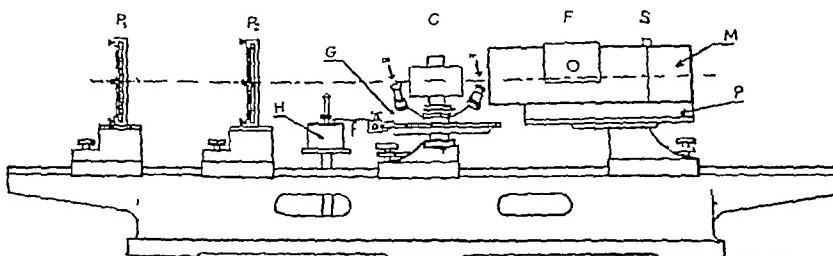

Fig 1 Spectrogram by rotating crystal method for diffraction of gamma rays

X-rays. The effects of certain gamma rays are perceptible through 10, or even 20, cm of lead. Thus, the coefficient of absorption in a lead screen is susceptible of falling to the value $\mu = 0.5$ cm for the very hard gamma rays of Radium C. Moreover, it seems that the law of variation of absorption proportionate to the cube of the wave length (law of Bragg-Pierce) is equally true for gamma radiation.

In general, the X- and gamma-rays exhibit the same properties, modified in the latter, however, by the effect of the extreme shortness of the wave length.

Hence the scattering of the gamma rays

has made use of the rotating crystal method and a spectrograph (Fig 1), which shows the considerable development of the collimating slit system the length of which reaches 25 centimeters. Figure 2 represents the gamma spectrum of the radiothorium. On the right side the rays have energies which do not exceed the energy of X-rays. A weaker line is observed, equal to 0.052 Ångstrom unit, the quantum reaching 236,000 volts.

However, when the frequency rises, the angles of diffraction on usual crystals (rock salt $d = 2.814 \text{ \AA}$) do not extend beyond a few tenths of minutes and measurements of

the wave lengths become altogether inaccurate. Moreover, the intensity of the lines weakens considerably, and the percentage of

tric effect presents here the same aspect as that of roentgen rays the author has verified that for the different elements, from copper to uranium. The kinetic energy of the photo-electric corpuscles is equal to the gamma quantum of the exciting monochromatic gamma radiation, diminished by the energy involved in extraction from the K, L, etc., levels of the element considered (relation of Einstein). In other words, the kinetic energies of photo-electrons coming from the most penetrating gamma rays scarcely differ from the energy of the incident quanta. The experiment is very easily demonstrated by surrounding a tube of small diameter, containing the radio-active substance, by a layer of the element to be investigated, for example, a sheet of lead or platinum. The velocity spectrum of the photo-electrons generated by this secondary radiation is obtained in a magnetic apparatus, similar to the one in use for corpuscular spectra for X-rays, which allows the gathering, at the same point, on a photographic plate of all the secondary beta rays which have been issued from the radiator at the same speed (Fig. 3).

The comparison of beta spectra, registered with different radiations, shows a displacement of all homologous rays towards the greater velocities when the atomic number of the element decreases (Fig. 4). This fact explains the corresponding diminution in the processes of extraction, K or L, of atoms.

These observations have also demonstrated that the spectral lines of beta rays, spontaneously emitted by radio-active substances of gamma radiation, were due to the conversion of the latter in the electronic layers of the radio-active atom.

Examined in a very light element, such as gas, the photo-electrons are relatively scarce compared to recoil Compton electrons. It is known that the relation of the numbers of secondary electrons of each of these types represents, for the radiations of

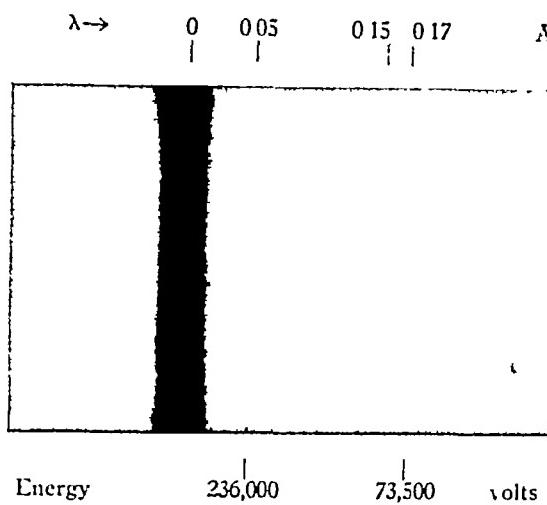

Fig. 2 Spectrum of gamma radiation of a radio-thorium preparation (rotating crystal)

electromagnetic effect in the spherical coefficient of gamma-ray scattering diminishes rapidly when the quantum exceeds 200,000 volts.

On the contrary, the effect of Compton scattering is particularly clear-cut: the recoil electrons acquire considerable speed. Photographed in the Wilson chamber, their trajectories present a rectilinear course, at times exceeding a decimeter, which distinguishes them clearly from the recoil electrons produced by the impact of the X-rays (fish tracks), measuring, at most, a few millimeters. The biologic effects of hard gamma rays must be attributed to these secondary scattered electrons travelling through the irradiated tissues like minute arrows, disseminating in the cells the ions generated on their way.

The gamma rays coming in contact with the tissues give rise to abundant secondary radiations and, particularly to an appreciable corpuscular radiation. The photo-elec-

high frequencies, the relation of coefficient of scattering σ and of absorption due to fluorescence in the radiating element. For

and that there are radiations of still higher quanta¹

Differing from X-rays, gamma radiations

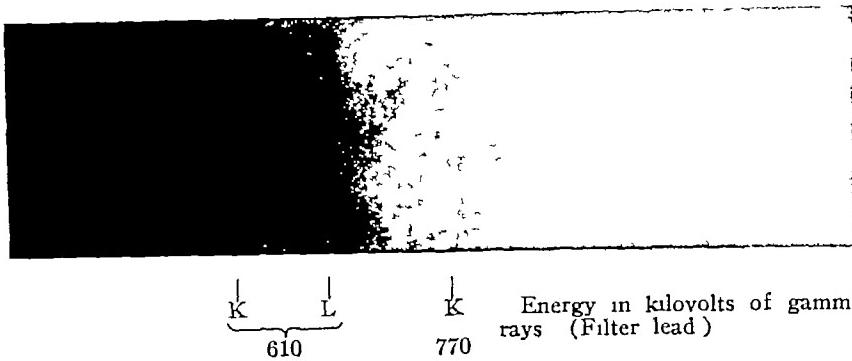

Fig 3 Photo-electric effect of gamma rays of radium

example, the relation of the coefficients σ/τ passes from the value 0.27 to the value 32, when the wave length diminishes from 0.7 to 0.1 Ångstrom unit. It is evident that for gamma rays this ratio can assume high values and that the number of the recoil electrons observed in the Wilson apparatus in a gas is extremely high compared to the photo-electric electrons.

The measurement of the wave lengths of gamma rays by diffraction in crystals is limited, as we have seen, to the less penetrating of these radiations. The most general method consists in determining directly the frequencies, beginning from the photo-electric relation of Einstein, by transforming the gamma spectrum to be considered into secondary electrons in a radiator of well-known levels of energy. In this manner, Ellis and Thibaud have been able to demonstrate the great number of gamma spectral lines in different radio-elements of radium and thorium families. The quantum of some of these radiations exceeds the enormous energy of 2,000,000 volts (wave length 0.006 Ångstrom unit). It is probable that only the inadequacy of our measuring instruments actually imposes this limit

emanate from much deeper atomic regions. Their origin must be attributed to energy exchanges generated in the very nucleus of the atom. Undoubtedly the study of such spectra will result in appreciable information regarding the dynamics of these still mysterious minute nuclei. Their complexity is certainly as great as that of the rest of the atomic structure. It already has been demonstrated in the absence of other guides that the principle of combination is applicable to different rays of the same spectrum. This translates the existence in the molecular domain of a subdivision in levels of energy or quantum states, repeating on a very much reduced scale the succession of electronic layers of Bohr.

Finally it seems logical to include in the category of gamma rays these extremely penetrating radiations of cosmic origin, which (for the present) are the end of the spectrum of known, very high frequency radiations. Their existence has just been definitely proved (Millikan, Kohlhorster). These cosmic, or ultra-gamma, rays to which is due the increasing ionization ob-

APPLICATION OF ROENTGEN RADIATION TO THE BARIUM-FILLED STOMACH

A CONTRIBUTION TO THE RADIATION TREATMENT OF INOPERABLE GASTRIC TUMORS

By THOMAS SCHOLZ, M.D., NEW YORK

THE most disappointing phase in the roentgen-ray treatment of malignant tumors has been the radiation results in inoperable gastric tumors. No matter what apparatus has been used and no matter what technic has been employed, the results, even in the most experienced hands, apparently have been not only uniformly negative, but in some instances the treatment has seemed to hasten the fatal course.

In view of such results it is no wonder that at the present time the consensus of opinion of roentgen therapeutists of wide experience does not favor radiation in inoperable gastric carcinoma. Pfahler (1) says:

*
In general, the intestine and the abdominal tissues will not stand the amount of irradiation necessary to destroy carcinoma of the stomach. We must obtain some addition to our present methods in order to accomplish such results. There is some hope in this direction.

Levin (2) declares

In my experience, high voltage X-ray therapy in carcinoma of the stomach has its value only as a post-operative measure, i.e., after the main tumor mass is removed surgically or else destroyed to a large extent by intramural radium insertion.

High voltage therapy, as well as surface or distance applications of radium in cases of advanced inoperable carcinoma of the stomach, has not given any satisfactory results as a general rule, though I did have a very limited number of cases in which there seems to have been a temporary improvement.

It frequently happens in my experience that a high voltage course either creates a cachexia or enhances the previously existent

cachexia. In view of all this I do not favor high voltage therapy as the only therapeutic measure in carcinoma of the stomach.

Wood (3) is of the opinion that "carcinoma of the stomach cannot be favorably affected by treatment with either type of radiation." And more recently (4) he states

I regret to say that I have never obtained results of any importance in irradiating carcinoma of the stomach. As a rule the patients are made more uncomfortable and I have abandoned treating such patients.

Forssell (5) in a recent article reviewing the irradiation results obtained in the Radiumhemmet at Stockholm makes no specific mention of gastric carcinoma. In Table IX of his article he classifies gastric carcinoma among that group of lesions in which surgery is the only applicable method of treatment.

My own experience in the treatment of gastric tumors dates back to the year 1915. From that time until the end of 1919 I treated with medium voltage rays, in the Lebanon Hospital and in private practice, altogether seven cases of inoperable gastric cancer without any appreciable results. Two of these patients, who were of advanced age and in whom gastro-enterostomy had been performed, died within 21 and 27 months, respectively, after the operation, while the remaining five younger patients, in whom only exploratory laparotomy had been done, succumbed within from two to nine months.

From 1920 until the end of 1922 I treated with high voltage rays six cases of inoperable gastric carcinoma. The results obtained

were, contrary to enthusiastic expectations, extremely disappointing. Radiation sickness became, in these cases, a more disturbing factor than before. In some instances it appeared as if the fatal course was hastened by treatment.

Of especial interest in this series was a case referred to me by Dr. Max Einhorn. The patient, a man 56 years of age, presented at the operation (performed by Dr. Willy Meyer) a large adenocarcinoma involving the middle third of the greater gastric curvature. A few days after application of a 115 per cent S.E.D. there appeared a brown discoloration of the body involving even those parts which had been protected by a heavy lead material. The discoloration gradually increased within the next two weeks and was associated with a very rapid decline of the patient's condition, followed by exitus five weeks after the operation.

This and other similarly disastrous results induced me at the end of 1922 entirely to abandon X-ray treatment for gastric carcinoma.

In 1923 there appeared an article by Holfelder (6) in which he, too, mentioned the uniformly disappointing radiation results in gastric carcinoma. At the same time, however, he pointed out that these poor results probably were due to an injury to the adrenals caused by the usual treatment technic. Experiments on guinea pigs had shown that the suprarenal glands cannot tolerate more than a 60 per cent skin erythema dose. In gastric carcinoma, therefore, he suggested the application of the rays at such an angle that the adrenals, or at least one of them, might completely be avoided. And in a later publication (7) he reported that with such a technic they have accomplished in gastric carcinoma "at least some results, while previously we have had nothing but disappointments."

MODIFICATION OF RADIATION METHOD

Holfelder's article gave food for new thought which gradually led to certain modifications of the technic in the radiation treatment of gastric tumors.

Taking it for granted that avoidance of the adrenals was essential for any successful radiation treatment in gastric tumors, it became evident that a reliable method for a definite localization of these glands in each individual case, would be of paramount importance. A few experiments with this objective indicated that the best way of accomplishing it would be by projecting in each instance the position of the adrenals and of the stomach upon the surface of the body. The position of the suprarenal glands could best be ascertained with the aid of a roentgenogram of the kidneys. By marking the position of the plate upon the patient's body before the exposure, one may transfer by means of a tracing of the plate findings the position of the kidneys upon the body surface. The outline of the stomach is marked upon the patient's abdomen directly by means of a contrast meal and fluoroscopy. Having thus obtained in visible form the exact location of kidneys and stomach and, therefore, also that of the adrenals and gastric tumor, one may easily succeed in arranging the direction of the rays so that at least one suprarenal gland may be definitely avoided.

During these experiments there also occurred the idea that it might be of value to increase the local X-ray effect in cases of gastric tumors by applying the radiation to the barium-filled stomach. As barium has a larger absorption coefficient than the tumor mass, there would therefore be produced in the barium-filled stomach a greater intensity of secondary radiation and a greater effect would be felt upon the adjacent tumor. This would possibly eliminate the necessity of high voltage rays and thus

increase the safety for the adrenals and also for the pancreas. Besides, the barium-filled stomach would in many instances almost completely protect the left suprarenal gland.

After deliberation it was decided at the beginning of 1924 again to take up X-ray treatment of inoperable gastric tumors, using the method just outlined, namely, surface localization of the adrenals and gastric tumor, selection of such a direction of the rays as to assure best possible avoidance of the adrenals, medium voltage rays, and application of the radiation to the barium-filled stomach. It was taken for granted that of the two types of secondary rays it would be the "characteristic" radiation which would mainly contribute to the increase of the local radiation effect. By very cautiously progressing with the dosage, it was hoped gradually to obtain a fair idea as to the therapeutic effect of the technic even without any previous experiments on the intensity of the secondary radiation.

The first case of "inoperable carcinoma" of the stomach treated with the above method was a patient in whom a gastro-enterostomy had been done. The patient is now, more than seven years later, in perfect health. Roentgen-anatomically the tumor mass has undergone a complete regression. However, as no microscopic findings were available, the case is published without any claims as to the nature of the lesion. The report, therefore, will be confined to clinical and roentgenologic facts.

REPORT OF CASE

History—Mr. A. P., 68 years of age, married, roofer by profession, always enjoyed good health prior to his present trouble. He drank beer and wine moderately, whisky very rarely, and did not smoke. Being of medium height, his weight normally used to vary between 156 and 160 pounds.

He ascribed the present complaint to a

severe injury to the abdomen sustained approximately two years previous to the examination. Local symptoms of that trauma disappeared within a few days. Nine months later, however, he began to experience an occasional "pain in the stomach," which had no relation to meals. He made no concessions to it, however, and continued his daily work.

After about five months he noticed a gradual loss of strength and weight, together with an increase in the frequency of the attacks of gastric pain which now seemed to become aggravated by food, however, his appetite still was good.

The following seven to eight months were characterized by intermittent periods of indigestion. In the meanwhile he had become accustomed to being "careful as to his food," and to restricting the amount of his daily work.

Approximately two months before the operation, he began to lose weight and strength more rapidly, the gastric pain became almost constant, appetite diminished, and constipation set in. He then decided to consult a physician.

Physical Examination—On palpation there was a moderately large, markedly tender, mass in the gastric region. Otherwise the examination was negative except for the suggestion of marked recent loss of weight (the patient now weighed 125 pounds) and an apparently greatly weakened general condition.

Laboratory Findings—Roentgen-ray examination showed "definite evidence of a neoplasm involving the pyloric third of the stomach, associated with very pronounced 6-hour gastric retention" (Fig. 1). Free HCl was present, though markedly diminished. There was occult blood in the feces. The blood picture was that of secondary anemia. The Wassermann test and urinalysis were negative.

A diagnosis of pyloric carcinoma was

Fig 1. Appearance of the stomach before operation showing almost complete obliteration of the pyloric third of the stomach outline.

made by Dr Max Krueger, the attending physician, and two gastro-enterologists. Immediate operation was advised.

Surgical Findings—Operation was performed on March 27, 1924, by Dr Alfred H Thomas, at the Staten Island Hospital. A tumor mass was found involving the pyloric third of the stomach, associated with marked and extensive enlargement of the regional glands. "The appearance of the tumor mass," Dr Thomas stated, "had all the characteristics of a large cancer, impossible to remove." A gastro-enterostomy was done. No tissue was removed for histologic examination.

The patient was referred for radiation treatment on April 24, five weeks after the operation. There was, at that time, a moderately tender, palpable mass in the mid-gastric region. He complained of slight oppression and pain after meals. His weight was now 121 pounds.

RADIATION METHOD AND ITS EFFECT

First, a projection of the renal and adrenal outlines upon the patient's abdomen and back was obtained in the manner described above. The patient then was given a barium meal. The stomach could hold only one-half of a glass of the contrast mixture. The plate findings as shown in Figure 2 are self-evident. The patient after-

ward was placed on a fluoroscopic table and the outline of the stomach was marked on the abdominal surface. The gastro-enterostomy stoma was found to be working well.

From the gastric and adrenal outlines thus obtained, it was evident that two portals of entrance—anteroposterior, with a slight tilt caudalward, and left lateral—would assure avoidance of the suprarenal glands in this case. In estimating the radiation dose to be applied it was deemed advisable to observe the rule of *nil nocere*, in view of the unknown factor of secondary rays produced by the barium-filled stomach. After considering all the various factors (which will be discussed more elaborately in a special paper), the following was decided upon mechanical rectifier, 145 KV peak, 5 mm filter, 50 cm distance, dose, 350 r.

The dose was repeated after four weeks and was again repeated five times at intervals of three weeks. Finding no reaction of any kind which could be attributed to the radiation treatment, five more applications under practically the same technical conditions were given at intervals of two weeks followed by a rest period of three weeks. When again no local reaction appeared, the roentgenologic appearance of the stomach remaining the same, though there was definite clinical improvement, the intervals between the radiation treatments were cut down to one week.

A few days after the third of these treatments, the patient began to complain of "pain in the stomach with a feeling of soreness," markedly aggravated by food. On palpation there was found very pronounced local tenderness, and, on fluoroscopic examination, very great gastric spasticity. The roentgen treatments were interrupted, the patient being put to bed and placed for three weeks on a fluid diet.

In the course of approximately two months, the acute symptoms gradually dis-

appeared There still remained a palpable mass, moderately tender to touch, and occasional feeling of oppression and pain after meals Roentgen-anatomical evidence, however, seemed now to indicate beginning

and the other two series were given during the last part of each year No treatments were applied during the months of June, July, and August A final two treatments were administered during the first half of

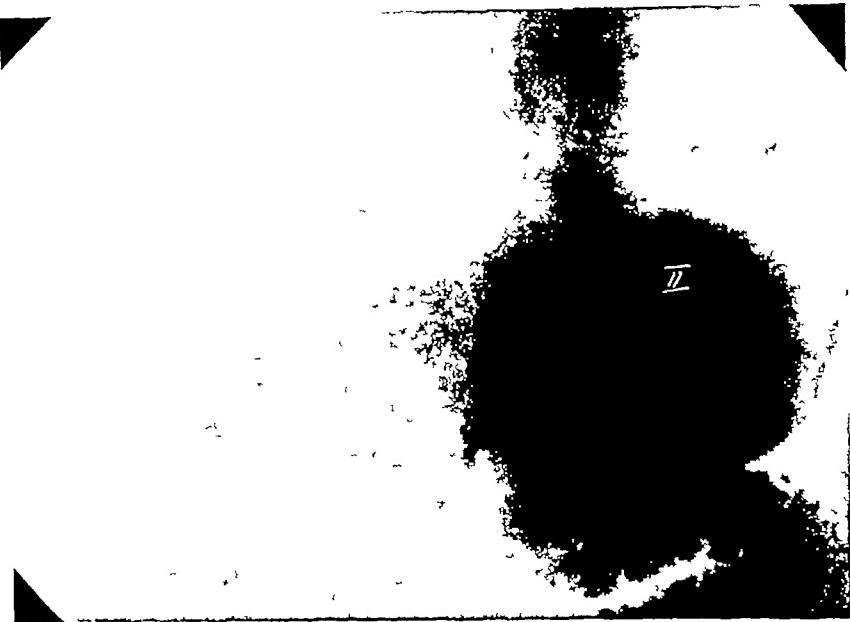

Fig 2 Appearance of the stomach after operation and at the beginning of the radiation treatment

regression of the tumor along its proximal periphery

The radiation treatment was taken up once more, the dose described above being applied every two weeks After the fourth treatment, there again appeared moderately marked permanent gastric pain The treatments were discontinued and within four weeks the pain again disappeared Roentgenograms now revealed more definite evidence of a recession of the tumor mass

On the strength of the experience gained so far, the treatments during the following years, until the end of the fifth year, were given in the form of four series each year Each series consisted of three treatments at intervals of two weeks Two such series were applied during the first part of the year, being separated by a longer interval,

the sixth year, approximately one and one-half years ago

The roentgenographic appearance of the stomach was watched by frequent X-ray examinations Following the first slight suggestion of roentgen-anatomic improvement, found approximately one year after beginning of the treatment, the regression of the tumor became more definite during the succeeding months It continued steadily until, at the end of the fifth year, there appeared, roentgenographically, to be a normal stomach (Figs 3, 4, 5)

The improvement in the general subjective condition of the patient was more rapid He considered himself perfectly healthy at the end of the third year Gastric pain disappeared within two years, palpable tumor within three years, and tenderness on

palpation within four years. At the present time, more than seven years after the operation, the patient is in excellent health, is of normal weight, and is able to do an amount of work which may be considered normal for his age, 75 years.

regression. Where there previously had been a solid tumor almost entirely obliterating the pyloric third of the gastric cavity, the latter was gradually re-established by the recession of the lesion to such an extent that, roentgenographically, there finally was ob-

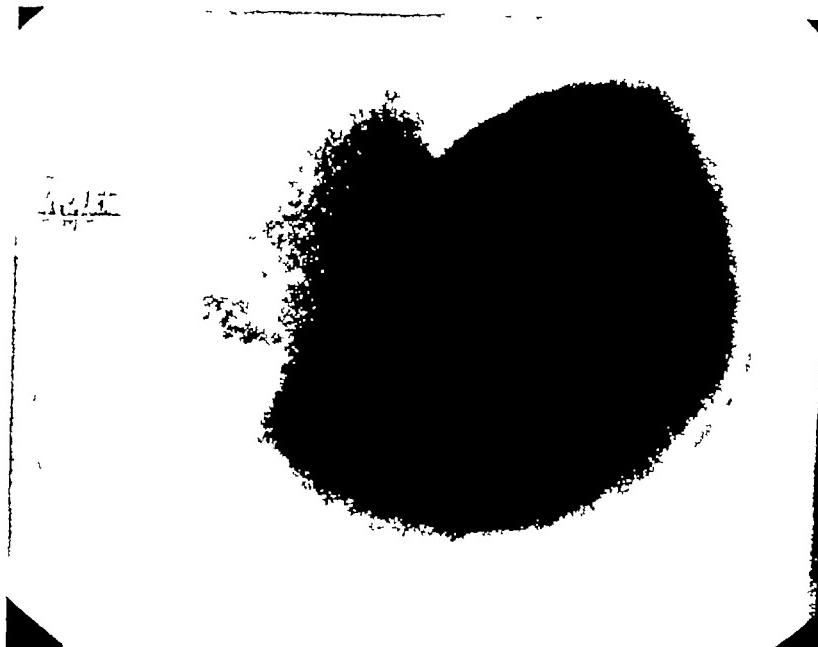

Fig. 3 Appearance of the stomach after two years of roentgen-ray treatment.

COMMENT

For a correct evaluation of the case just reported, various points have to be taken into consideration.

In view of the lack of microscopic findings, one cannot, of course, definitely consider the lesion one of gastric carcinoma. However, its characteristic clinical course, its macroscopic appearance as observed by an experienced surgeon, and the extensive involvement of the gastric and mesenteric lymph nodes make it more than probable that the condition was of a malignant type.

As to the therapeutic result, there is no doubt but that clinically a cure has been accomplished and that roentgen-anatomically the tumor mass had undergone a complete

tained normal pliability and peristalsis of the entire gastric wall.

As to the causes for these gratifying results, all those factors ought to be taken into consideration which might possibly have contributed to them.

First, the patient's age was a favorable factor, because it is a well-known fact that, with advancing age, the malignancy of cancer as a rule decreases, while at the same time the tendency towards regression increases.

Secondly, spontaneous regression in carcinoma, as pointed out by Lohmer (8), Rohdenburg (9), and Trinkler (10), may have played an important rôle in this case, too. This point is of greater importance than is generally realized. A careful study

Fig 4 Appearance of the stomach four years after beginning the X-ray treatment

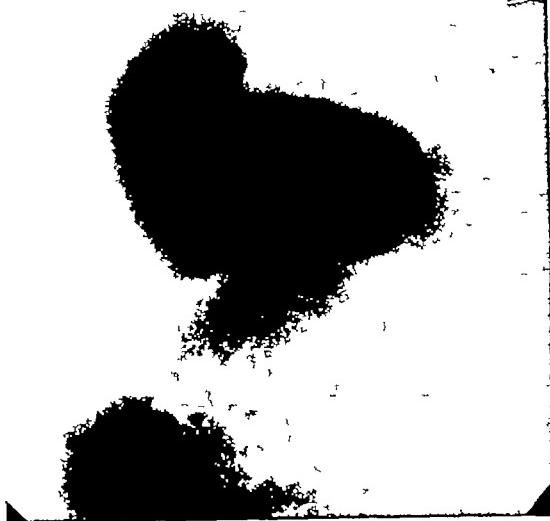

Fig 5 Appearance of the stomach at the end of the fifth year

of the instances of spontaneous cancer cures reviewed by the above authors definitely shows that the human body is not absolutely helpless against the carcinomatous growth. On the contrary, there seem to be factors, not properly understood yet, which apparently aid in or give the first stimulus for the regressive process. A more thorough study of these conditions will go far toward a proper understanding of the cancer problem. Such a study may prove of especial value in gastric tumors, because, as Ewing (11) has pointed out, and systematic X-ray examinations have shown, gastric cancer, more than any other cancer, is characterized by an intermittent growth. There often are long periods during which the growth remains stationary. Factors aiding regression brought into play during such stationary periods may become invaluable.

That gastro-enterostomy in inoperable gastric cancer occasionally is followed by a remarkable improvement, sometimes bordering on a complete cure, is a well-known fact. During my own observations, over a period of more than 20 years, in a large number of cases of carcinoma of the stomach, especially among the extensive material of the Montefiore Home, I have seen such patients remain alive for a long time almost sym-

ptomless, as much as from three to five years after the operation. This would tend to support the theory of chronic irritation, because there is no doubt but that a gastro-enterostomy, especially in obstructive pyloric carcinoma, greatly relieves the irritating factor. We would have to admit, therefore, that in our case, too, the gastro-enterostomy may have played an important rôle.

The general medical care and handling of the patient has, of course, a great influence upon the therapeutic outcome. General measures for the purpose of strengthening the patient's vitality and increasing his power of resistance along the lines recently suggested by Jackson and Minot (12) are extremely helpful. Ease of digestibility and elimination of irritation possibly arising from certain articles of food should be important guiding factors in the selection of the diet. Conditions in this respect were in our instance, fortunately ideal.

Finally, in regard to the X-ray treatment there is no doubt but that it has played a rôle

in the therapeutic accomplishment. This is demonstrated by the fact that the regression set in only after an apparently sufficient amount of radiation had been applied. Furthermore, that the "characteristic" secondary rays probably were of decisive importance is suggested by roentgen-anatomic evidence to the effect that the regression started along the proximal periphery of the tumor and then gradually progressed towards the pylorus. In other words, the regressive process always was taking place along the contact line between tumor and barium. Besides, this radiation method has so far been used in five additional cases with apparently encouraging results. The dose, however, has since been slightly modified.

It would lead too far afield here to touch upon all the problems involved in the radiation treatment of the barium-filled stomach. A more detailed discussion of them will be published after the completion of certain experiments which are being carried on in collaboration with Dr Arthur Mutscheller. Besides barium sulphate, bismuth-subcarbonate was used as a contrast medium. Experiments also were made with mixtures consisting of barium or bismuth, and other metallic powders, in an attempt to ascertain the best possible type of fluorescent radiation. In this respect, magnesium oxide, in its heavy and light forms, and calcium, seemed to give favorable results.

CONCLUSIONS

1. Roentgen radiation applied to the barium-filled stomach in inoperable gastric tumors seems to aid in the bringing on of the regression of the tumor mass.

2. Avoidance of the adrenals in the application of radiation to the stomach is of great importance.

3. The best way to avoid the adrenals is by definitely determining in each individual case the exact position of the suprarenal glands and of the stomach. This can be readily accomplished by projecting the outline of these organs upon the surface of the body.

ON INTRATHORACIC LOCALIZATIONS BY STEREOROENTGENOGRAPHY, WITH A CONSIDERATION OF THE SOURCES OF ERROR

By HENRY C SWEANY, M.D., ROY KEGERREIS, M.D., and CARROLL E. COOK, M.D., CHICAGO

From the Research Laboratories of the Chicago Municipal Tuberculosis Sanatorium,
Chicago, Illinois

T has been observed by many working in roentgenology that stereoscopic radiographs commonly produce effects that are obviously faulty and illusory. We frequently encountered such troubles during the course of some recent work on the exact localization of cavities in patients with pulmonary tuberculosis, which involved the study of stereoscopic radiographs (1). In this work, mensuration was attempted on 250 pairs of stereoscopic radiographs, but 14 were found to have such pronounced distortion that a good deal of the contents of the thoracic cage was projected beyond its confines. This represents about 5 per cent of the total number, and we believe that it is a fair average for routine institutional work. It should be explicitly stated that very pronounced distortion existed in these 14, there were, of course, many more that were not rejected or even detected because of only very slight distortions. So far as we are aware, no analysis or explanation of such phenomena has ever been made. The problem seems to be of sufficient importance to merit such attention, inasmuch as stereoscopic X-ray examinations are among the most valuable aids in this branch of medical diagnosis.

The discovery of discrete pulmonary lesions that appeared to be outside the bony thorax when viewed stereoscopically led us to make observations on the other structures shown in these stereoscopic views. It was found that either one or more of the following conditions existed:

1. The ribs had shifted more than usual.

2. The width of the chest had altered.

3. The domes of the diaphragm had shifted anomalously.

These are all caused by the patient making respiratory movements between exposures, the most common cause being diaphragmatic breathing. Independent of the respiratory movements, and perhaps more common, but less marked, are disturbances which are caused by the heart beat.

A brief review of the principles involved are given for the sake of clarity. Stereoscopic observation is an attempt to reproduce normal vision by means of a pair of photographs so that normal plasticity will be revealed. It is a well known physiologic and psychologic fact that a realization of the third dimension in stereoscopic vision is largely a matter of education and experience. The realization of plasticity, or the judgment of depth, by one person may be more accurate than by another, the relations of objects to one another, regardless of the observer, however, will be proportional, so that correct ratios will be the same in the case of two observers. There is no established usage for the exposure of the two films of a stereoscopic pair, and the distances used for the target-film distance and tube shift are so different in the various laboratories that each worker forms his estimates from the sort of usage to which he is accustomed. The distance between the eyes is very nearly the same in all observers, and, accordingly, our judgment of distance in naked-eye vision is always based on the same

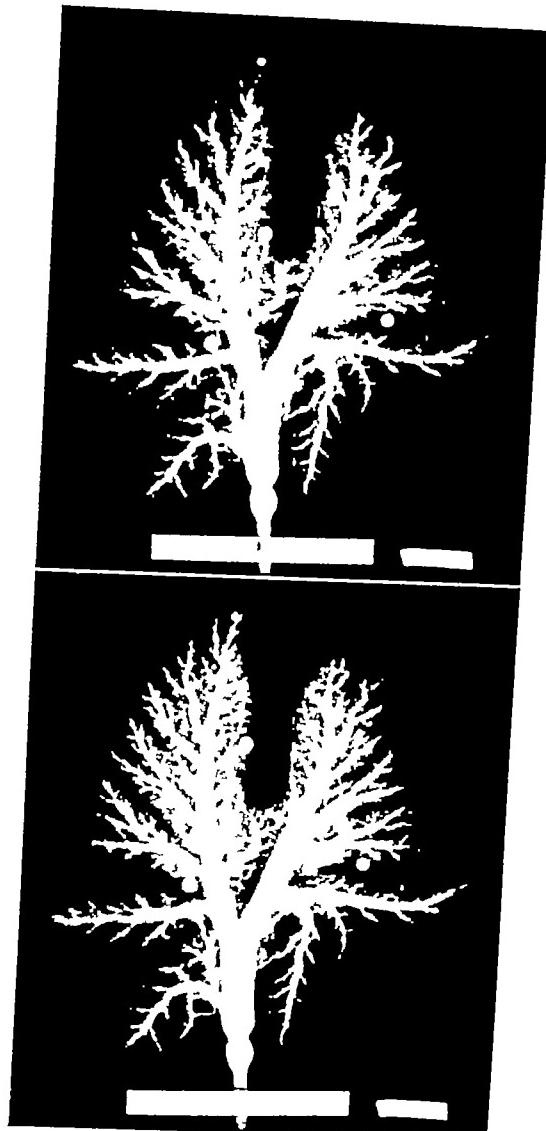

Fig 1. Photograph of a pair of normal stereoscopic radiographs of a hog's lung, containing lead pellets, and injected with dental cement, reduced for viewing in a hand stereoscope

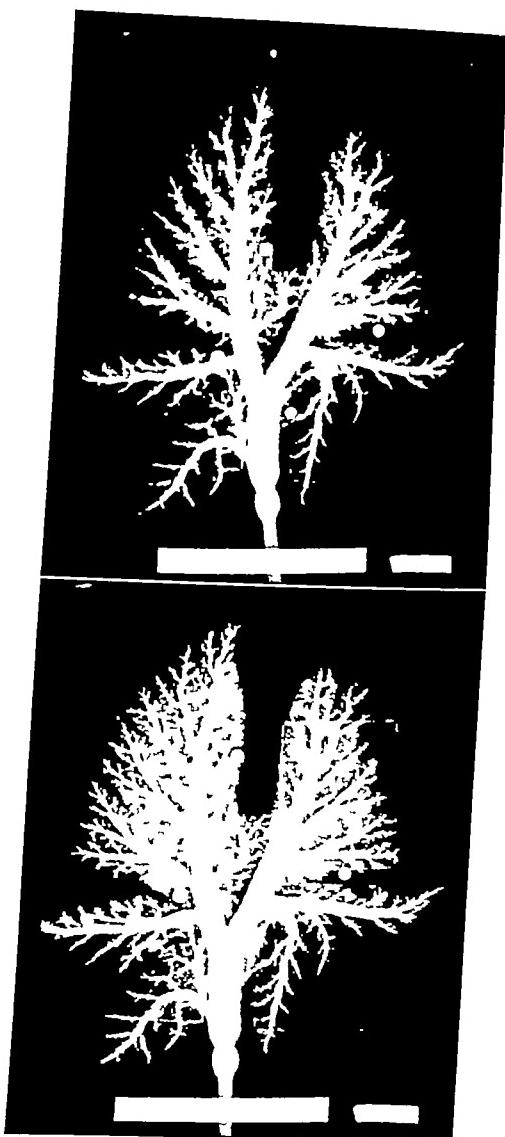

Fig 2. Same as Figure 1 except that traction was put on the lower lobe at Pellet No. 1, and the tip was pulled down 2 cm., resulting in marked distortions

distance apart on the datum line, which, of course, is not the condition in X-ray stereoscopy. This phase of the subject has been ably discussed by Stephenson (2). It was Helmholtz (3) who first thoroughly explained the physiology of binocular vision, showing that the viewing of an object from two slightly different angles will give it plasticity. Elihu Thomson (4) was the first, in 1896, to attempt the application of

stereoscopic vision to X-ray work. He was followed by Davidson (5) in 1897, who successfully utilized the now familiar Wheatstone reflecting stereoscope and, incidentally, pointed out the distortion which is caused by motion between exposures. Also, his method for the localization of foreign bodies has been a model for many others.

The type of distortion depends on the direction and extent of the motion, for ex-

ample, the normally resulting stereoscopic shift is exaggerated on the radiographs when the tube shift is downward (which is the universal practice) and the diaphragm motion between exposures is upward, as is the case when the patient exhales. In this event the contents of the thorax will appear to be abnormally posterior, or nearer to, the observer. In extreme cases the bases of the lungs will appear outside the posterior ribs.

On the other hand, if the diaphragm moves downward (inhalation), the contents of the thorax will appear to recede from the observer and to be displaced anteriorly in the patient. This tends to annul the normal stereoscopic shift, resulting in a loss of depth. If the normal stereoscopic shift is just annulled, the object viewed will appear to be in the plane of the film, which is anterior to the chest. Furthermore, if the downward motion of the diaphragm causes a greater shift than the normal stereoscopic shift, the object will appear far anterior to the patient's thoracic cage.

In a similar manner, the movements of the heart will cause a distortion of the heart shadow and adjacent lung tissue, unless the exposure happens to be at exactly the same phase of the heart cycle. Such cardiac movements, however, are in no way related to the movement of the bony framework of the chest or the diaphragm, and may be

in any direction instead of parallel to the shift.

In the examination of a pair of stereoscopic radiographs of the chest, therefore, there are several preliminary scrutinizing observations that should be made. First, one should see that all lateral dimensions of the bony framework are identical, that is, the distance between the scapulae, the overall width between any pair of ribs, or the lateral distance of any object to the ribs, or midline, should be exactly the same on both. This is usually not true if respiratory movements of any kind have taken place.

EXPERIMENTAL

After rather extensive experimentation, we were able to prove the above-mentioned theory by a simple experiment. First, we used hogs' lungs in such a way that the various measurements could be obtained absolutely as well as geometrically and stereoscopically, and, second, we were able to apply this information to a practical problem on a patient who had a disseminated, partially healed, small, nodular pulmonary tuberculosis.

Experiment 1—In a hog's lung (fresh) the bronchial tree was filled with an "artificial stone"¹. This was placed over an improvised tunnel for the X-ray film holder, on

¹This product is a slow setting dental cement.

TABLE I—MEASUREMENT OF PELLETS IN HOG'S LUNG

| Pellet number | Estimated Stereoscopic observation | Calculated | | | Measured | | | % error between calculated and corrected measure |
|---------------|------------------------------------|------------|------------|---------|----------|-----------------|-----------------|--|
| | | 2-in shift | 4-in shift | Average | Distance | Correction | Corrected value | |

top of four halves of pasteboard microscopic slide boxes one inch deep, a number of lead pellets were placed at different levels throughout the lung and directly over the film. One pellet was suspended above the

Column 5 The actual distances according to measurement are in Column 6, with corrections in Column 7, and the corrected values in Column 8. The correction is due to two things first, the sag in the top of the

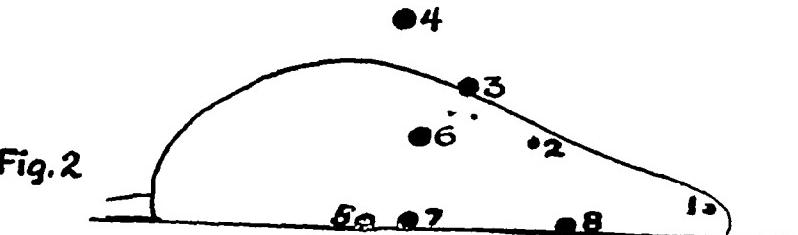

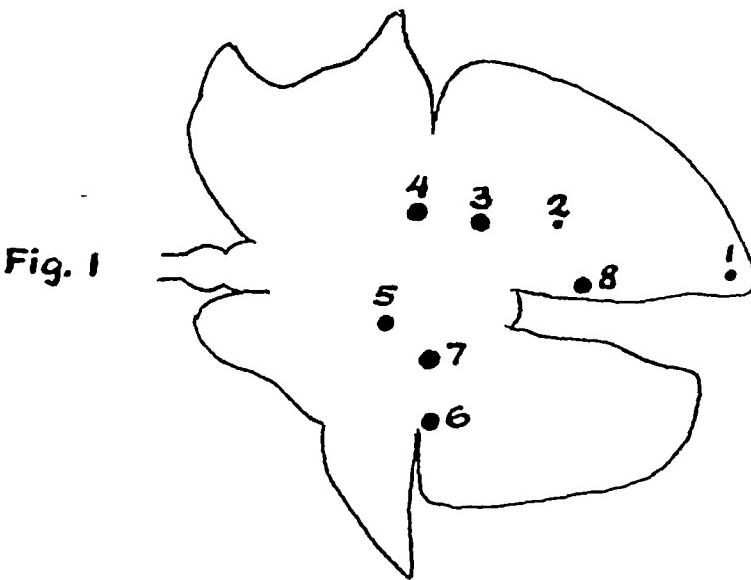

Chart I Diagrammatic sketches of Figure 1, showing the positions of the lead pellets Fig. 1, anteroposterior view, Fig. 2, lateral view

top surface by means of cross-threads. The distance of each above the film was measured, and then stereoscopic radiographs were made, using a 40-inch focus-film distance, and four- and two-inch tube shifts, respectively. The measurements and calculations are tabulated in Table I. The estimated distance by stereoscopic observation is in Column 2, the distances calculated by measuring the shifts are compared in Columns 3 and 4, with an average in

X-ray table, which was actually about 4 mm, and, second, the half diameter of all the pellets, because the measurements were made from their tops and not the equatorial plane which casts the shadow.

Pellet No. 4 was suspended by cross-threads above the whole lung specimen, but no doubt was moved in shifting, as a movement of only 1.5 mm would account for the discrepancy between the shift value and the actual measurement. The position of Pellet

No 8 is purely illusory. It was simply rolled along the film parallel to the shift, and appears far out toward the observer. These conditions are shown in Figure 1, which is so arranged that it may be viewed

posterior and lateral views of the specimen shown in Figure 1

Experiment 2—With the lung in the same position as in the second exposure, a thread was attached to the tip of one of the right lobes, and the tip pulled downward parallel to the direction of the tube shift (inhalation), a distance of 2 cm., and while it was in that position a third exposure was made. This is shown in Figure 2, which also is placed so that it may be viewed by a hand stereoscope to show the real and illusory positions of the various objects. The lung appears extremely distorted, which can be explained only when the movements are understood. The pull on the tip of the right lung stretched the whole right side downward with the shift, the bronchus and adjacent parts stretching the most with the displacement, gradually diminishing upward towards the trachea. This was possible because the cast was not completely "set." The outer and upper parts of the lung either lagged behind, or were actually tilted in the opposite direction. This combined effect would produce three distortions, *viz.*, (1) posterior, (2) loss of plasticity, and (3) anterior. The posterior distortion (*i.e.*, appearing toward the observer) is due to the lack of movement or movement opposite the shift, and is shown by the curling up of the tips of lobes toward the observer, as well as a nearer view of Pellet No. 4, which was suspended above the lung. The loss of plasticity is due to the movement of the main bronchus with the shift. When this movement is equal to the shift displacement, there is no plasticity. The object then appears flat and in the plane of the film (Pellets Nos. 2 and 3). When this shift displacement has been equalized and greatly exceeded, as in Pellet No. 1 and the tip of the lobe, they appear anteriorly (or away from the observer).

Fig. 3. Stereoscopic X-ray view of patient with disseminated nodular tuberculosis, after exhalation (crusing the diaphragm). The contents appear to be posterior.

with a hand stereoscope. Chart I is a diagrammatic sketch, to show the anterior-

After this demonstration the study was directed to an actual living example, and we

were so fortunate as to find a suitable patient.

Experiment 3—A series of exposures under different conditions were made as follows. First, a double exposure was made

correct exposure (shown by the dotted lines).

Subsequently, we observed that certain distortions took place even when respiratory and other external movements were con-

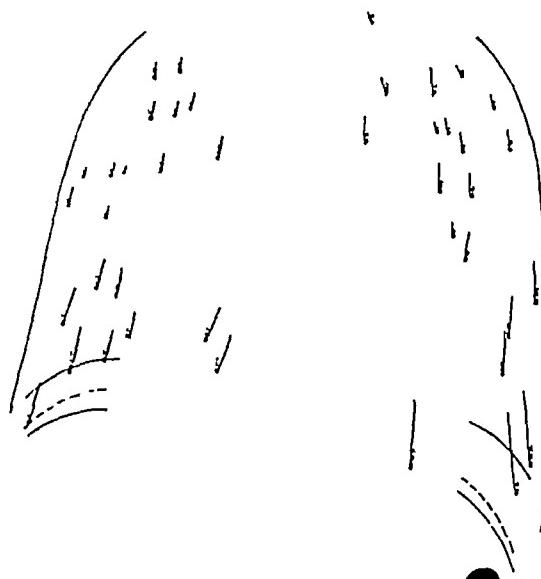

Chart II. Sketches of double exposures taken of the patient shown in Figures 3 and 4. Dotted lines show the shift of the tubercles on a normal exposure. The solid lines show the shift of the same tubercles on rising the diaphragm (exhalation).

on the same film, one exposure before and one exposure after the shift. This doubly exposed film enabled us to measure the shifts of various shadows on one film with considerable accuracy. These are shown graphically by the dotted lines in Chart II, and reveal the fact that some of the shadows shift much more than others.

Experiment 4—Two more sets of exposures were made, one with inhalation (lowering the diaphragm) and one with exhalation (raising the diaphragm) between exposures. The latter is shown in Figure 3, and reveals the fact that the position of much of the contents of the thorax appears to be posterior to the posterior ribs. The total shift of many of the shadows is shown by the solid lines in Chart II. There is about three times as much shift as in the

Fig. 4. Same as Figure 3 except that respiratory and cardiac movements were controlled as much as possible and so the contents appear in reasonably normal position.

trolled. It was first suspected, then demonstrated, that the heart movement produces almost as much distortion as do movements of the diaphragm. In fact, when there is

otherwise good technic, this factor is the most common source of distortion, and one that has not been exhaustively studied²

In this report we have made no attempt to "control" the heart movements with respect to the exposures further than crudely to expose pairs of radiographs in the same and in diametrically opposite phases of the cardiac cycle. The effect of this movement has wide possibilities, depending on whether the movement resulting is *with* or *against* the shift of the target. The vertical component of a movement *with the shift* will produce only a loss of plasticity, while displacement *against* the tube shift will project the image further posteriorly, depending on the amount of the displacement. For example, if the shift displacement on the radiographs is 1 cm., and the movement caused by the heart is 2 mm. (one-fifth the former), the lung would appear one-fifth, or 20 per cent, out of the chest posteriorly, and proportionally so for any other distance. With the first exposure during the height of systole, and the second similarly in diastole, the shift displacement would be lessened, with only a reduction of depth or plasticity. In addition to the vertical, there are other components that we have not attempted to study.

To test some of these hypothetic considerations, we performed two experiments in an attempt to establish them as facts.

Experiment 5—A "normal" was made in which both films were exposed in approximately the same period of the heart cycle, the exposure being manually controlled by observing a blood pressure manometer. Although there is still slight distortion, the stereoscopic visualization is much more nearly correct than in Figure 3, in which deliberate respiratory movement had taken place.

Experiment 6—Two exposures were made on the same film, approximately a half-second apart, so that the exposures would occur in the opposite phases of the heart cycle. There resulted a maximum of blurring and duplication of the shadows, especially in the right side, with an average displacement of about 3 millimeters. The direction is parallel to the shift throughout most of the field, but near the periphery it is more oblique or horizontal. Why the left side did not react in the same manner, we are unable to state, but it seems always to be so, and, of course, is dependent on the anatomic arrangements.

Experiment 7—Another experiment was performed in which stereoscopic views were taken in the same phase of the cardiac cycle. Here the exposures were made in approximately the same phase and were reasonably correct (Fig. 4). All of these displacements can be explained, however, on a basis of movement with or against the shift between exposures.

Factors that may exaggerate the distortion by cardiac movements are consolidations or adhesions between the pericardium and the lung, or between the pericardium, lung, and thoracic wall. Each different possibility of anatomic aberration will be reflected in a different type of distortion unless the exposures are made at exactly the same phase of the cardiac cycle. Up to the present time, however, there is no simple, accurate means of accomplishing this, and until this is effected, exact localizations in the region of the heart will be impossible. Upper lobe lung localization can be accomplished, however, with a fair degree of accuracy, because these lobes are not disturbed so much by cardiac movements. In viewing a pair of radiographs caused by a diaphragmatic movement, distortion is not evident until the hilum is approached from above. Below the hilum it becomes gradually more marked. The distortion due to

²Since this work was completed we have learned of the excellent work of McPhedran and his associates which aims to eliminate this source of error.

cardiac movements is more marked near the heart, but may be quite irregular if there are adhesions present, when the distortion varies with the extent and location of the adhesions

DISCUSSION

Some of the important lessons of these studies are the bearing they may have on intrathoracic localizations and the interpretation of distortions appearing in routine stereoscopic examinations. As a result, more accurate localizations of lesions are made possible if unsatisfactory radiographs are discarded. Unless these distortions are recognized, however, localizations within the chest will frequently be difficult, if not impossible, to perform within a sufficient degree of accuracy to be of practical value. Respiratory movements are easily controlled and should offer no obstacle to accuracy. By superimposing the bony landmarks, such as scapulae, clavicle, greatest width of thoracic cage, etc., such movements may be easily detected and the faulty radiographs discarded. The heart movements, however, are entirely different, because they are not under the control of the operator, and their detection is not so easy since no signs of them are apparent in the bony framework. There is no sure method of control except to attempt to obtain the exposures in the same phase of the cardiac cycle. This is difficult to do and our attempts have been very unsatisfactory except to point out the possibilities of such movements. Localizations near the heart are, therefore, unreli-

able, and, if fibrous adhesions exist either between the pericardial and visceral pleura or the visceral and parietal pleura, the situation is further complicated. Movements of from 2 to 3 mm. will produce gross distortions.

SUMMARY AND CONCLUSIONS

Evidence has been offered revealing various types of distortion of stereoscopic X-ray images in radiographs of the chest. Assuming that the exposures are taken in a correct manner with optimum tube shift and distance, and that the viewing apparatus is properly adjusted and correctly used, there are still possibilities of error due to movement between exposures if certain precautions are not closely adhered to. These errors are due to three types of movement: respiratory, cardiac, and that of the trunk as a whole. Cardiac movements are quite variable, but many times, if adhesions are present, they interfere with any localization around the heart. The type of distortion depends upon the direction of the motion, which, in turn, depends on the relative phase of the cardiac cycle at the instant of exposure.

ROENTGEN DIAGNOSIS AND TREATMENT OF PERSISTENT THYMUS

By M J HUBENY, M D, CHICAGO, ILLINOIS

CONTROVERSIAL issues abound in medicine no less than in other scientific endeavors, and this is said without disparagement. In some cases the unquestionable association of cause and effect is convincingly established and needs no further elucidation or defense.

Ever since 1614, when Plater reported a sudden death, without apparent cause, in a five-months-old child, in whom necropsy revealed an enlarged thymus as the only abnormality, considerable discussion has clouded the issue of status thymicolymphaticus, which was first advanced as a definite clinicopathologic entity by Paltauf in 1889. The latter described this condition as due to a decreased resistance of the body to shocks or injuries, dependent on a specific constitutional anomaly, shown anatomically

by prominent thymic and lymphatic tissue. This has been generally accepted.

However, in 1926, the British Medical Research Council and the Pathological Society of Great Britain and Ireland appointed a joint committee to investigate status lymphaticus. The object was to establish by means of a large series of weights and measurements the standards for age and proportion to body weight of the normal thymus at all ages, also to investigate closely the cause of death in persons dying suddenly from unexplained or seemingly trivial causes, wherein the only apparent abnormality was the presence of a large thymus.

The committee determined that, in the normal series up to sixteen years of age, there appears to be little, if any, association

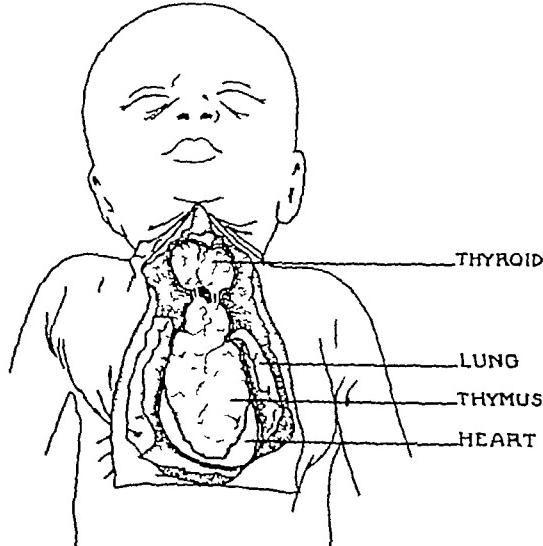

Fig 1 Showing relation of the thymus to some of the neighboring structures

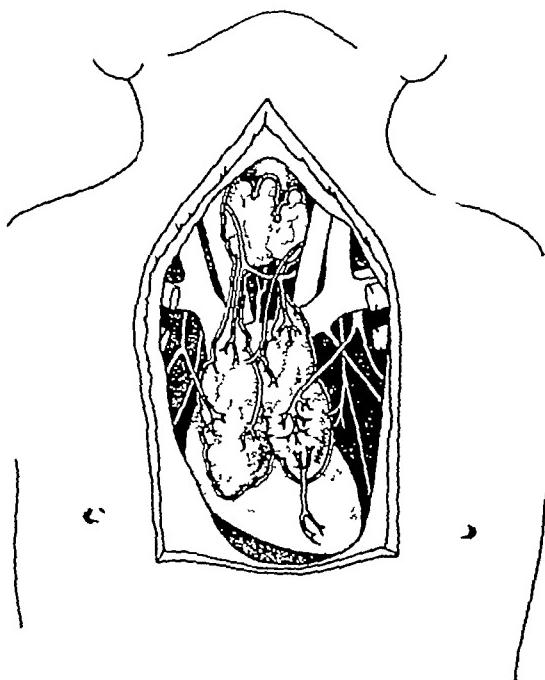

Fig 2 Detailed dissection showing nerves and carotid and innominate vessels
(From Crotti)

between the weight of the thymus and the amount of lymphoid tissue in the various parts of the body, insofar as this amount can be indicated by volumetric measurements of the faucial and lingual tonsils, selected lymph glands from certain sites, Peyer's patches, etc. The few data available show no concomitant general hyperplasia of lymphoid structure in cases with abnormally large thymus. They concluded that in many cases of Graves' disease the thymus was large, due to increase in glandular tissue, yet there was no definite general hyperplasia of lymphoid structures. They also agreed with Hammar and Greenwood, and Woods, that there is no evidence that so-called "status thymicolymphaticus" has any existence as a pathologic entity.

So, for the sake of agreement, let us acknowledge that there is such a thing as an enlarged thymus, since this committee has recognized its occasional presence, as have roentgenologists, also, certainly, pediatricians have clinically recognized its existence for a long time.

Noback has shown that the lobation of the thymus is determined early in fetal life, that the bilobed type of thymus predominates and that its location is most frequently cervicothoracic. The organ is distinctly broad in outline, extending laterally as far as the anterior axillary line in most cases, and is practically never overlapped by fetal lungs. This distinctly broad type of thymus, described as being the fetal type, he also showed to be typical of full-term, stillborn babies.

The thymus of infants in whom respiration has been established is usually cervicothoracic in location, is elongated in form, and bears the impress of the organs with which it is in contact. The right lung extends on its anterior surface in every case, the left lung extends over its anterior surface in four out of five cases. The thymus overlaps the right ventricle of the heart in

more than 50 per cent of cases, and on the left side in more than 75 per cent.

The change from the broad type to the elongated type of thymus, found in the individual who has breathed, is accomplished during the period of time in which respiration is completely established. The expansion of the lung changes the position in relation to the thoracic contents, and, along with the other organs and viscera of the thorax, the thymus is markedly affected. It is compressed both laterally and anteroposteriorly, requiring a certain amount of molding.

Noback believes that, in the neonatal period, the degree of expansion of the lungs is a more potent factor in determining the lateral extent of the thymus than the actual size of the organ and, during this period at

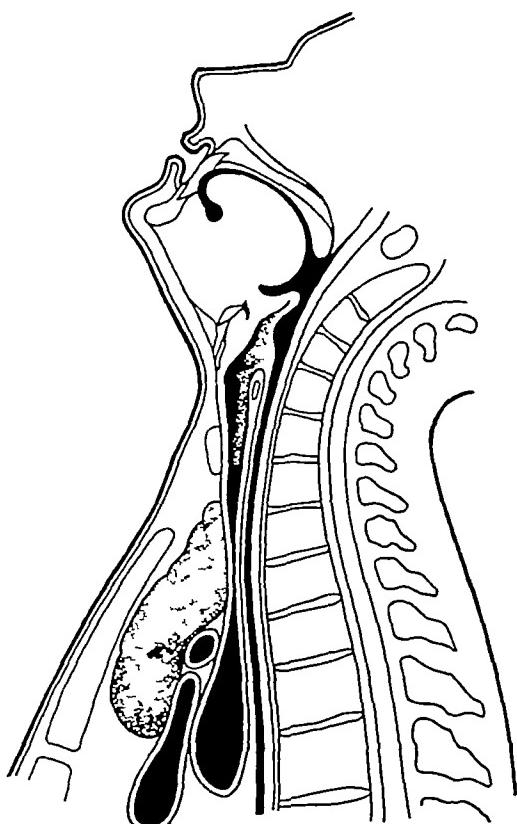

Fig. 3 Normal relation of thymus. Any increase in size would cause pressure symptoms at anterior spur triangle.

least, the thymus, lying in the usually described normal area, may exert marked pressure on the structures posterior to it. This may be due to an unusually large thymus or to a very narrow superior thoracic aper-

dium over the base of the heart and great vessels. Noback says that in exceptional cases it extends to the left vagus nerve. On the right side it is generally found to be close to the superior vena cava, the left in-

Fig. 5 (lower) Various forms of tracheal ring architecture

ture, which will not allow the thymus to protrude into the cervical region, as it is compressed by the expanding lung.

Late in fetal life and in the unborn the thymus is related posteriorly to the pericar-

nominate vein and occasionally the superior vena cava being embedded in the posterior aspect of the thymus. In a few cases, he found that these vessels actually ran through the substance of the gland. The innominate

Fig 6 In this case the spinal deformity confused the diagnosis, however, treatment was given, with abatement of symptoms.

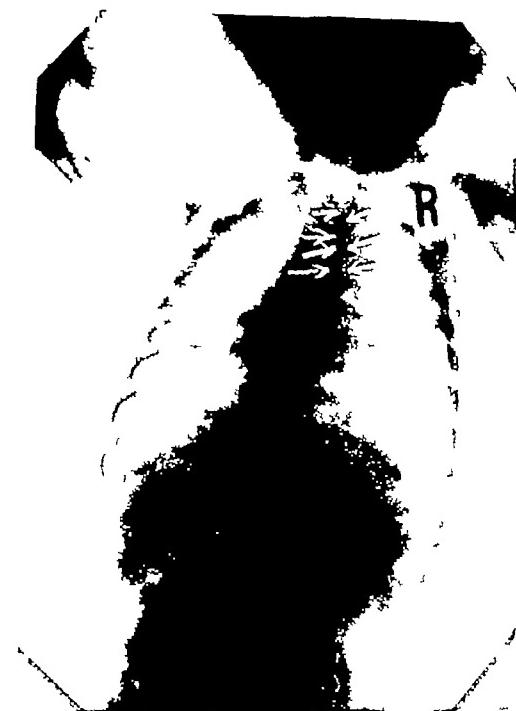

Fig 7 Note tracheal displacement.

artery is closely applied to the trachea and crosses it diagonally, and the left innominate vein passes across the artery at the level of the upper border of the sternum. An increase in the anteroposterior extent of the thymus in this region would, he says, due to the rigidity of the superior thoracic aperture, compress the above-named structures.

Jackson states that tracheal collapse in infants is as easy to accomplish as collapse of the bulb of a medicine dropper, also, thymic deaths under anesthesia attributed to status lymphaticus and hyperthyroidism of the blood are nothing more or less than arrested respiration due to obstructive pressure of the engorged thymus. In view of these observations and their confirmation by roentgenologic studies, the compression theory is tenable.

At this point it might be desirable to call attention to the work of Heller and von Schrotter regarding the anatomic structure

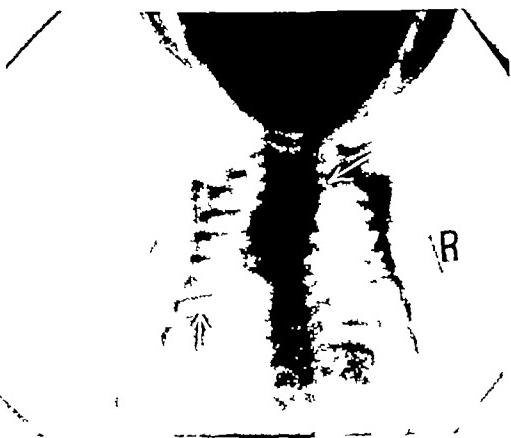

Fig 8 Thymic enlargement is toward the right. Signs of rickets are present.

of the trachea and bronchi. Their results may be summed up as follows:

If the trachea is cut off 2 cm above its division, an exact view of the place of bifurcation is afforded. One sees, looking at such a preparation from above, a nearly sagittally arranged larger or smaller ridge dividing the

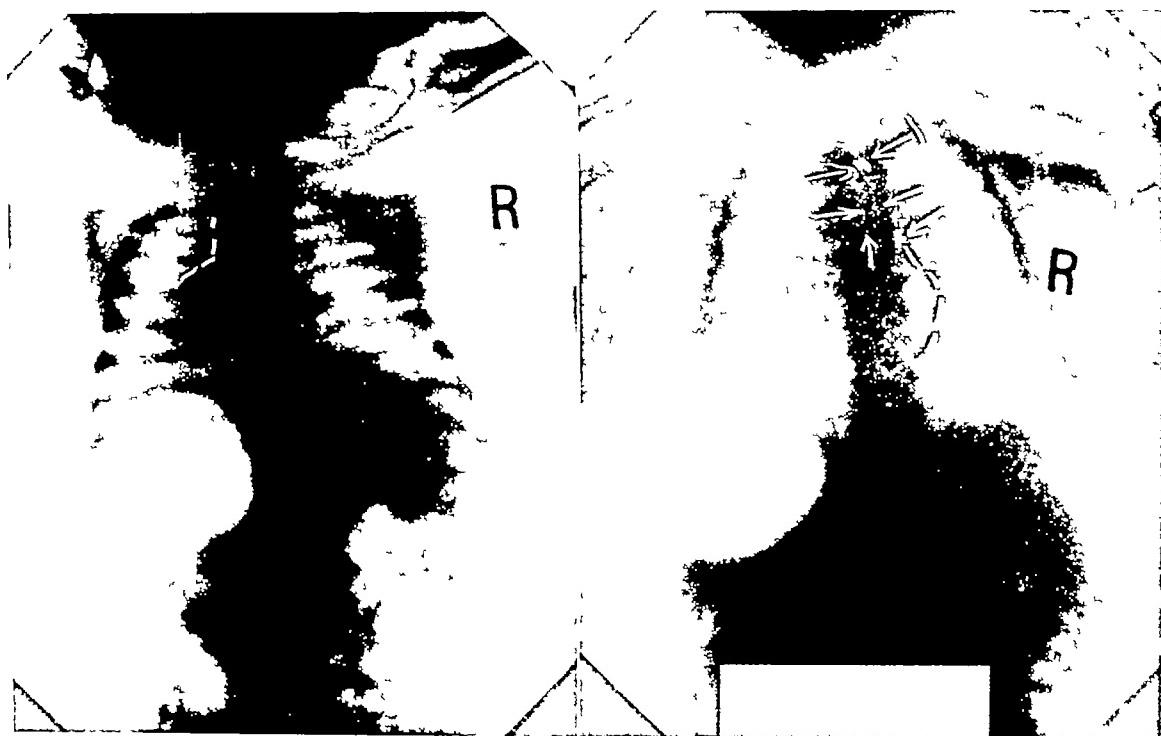

Fig 9 Thymic enlargement is toward the left

Fig 10 Enlargement is essentially to the right.

Fig 11 Marked bilateral enlargement

Fig 12 Same case as shown in Figure 11,
three months after treatment.

lumen of the trachea. The walls of this ridge enlarge toward the anterior wall of the trachea into a more or less triangular surface which is designated as the "anterior spur triangle", toward the posterior wall the edges of the

the outer angle which corresponds to the division of the bronchi

Out of the 125 human tracheæ investigated, the spur was found to be cartilaginous in 56 per cent, membranous in 33

Fig 13 Note the enlargement present

ridge diverge less, and there thus arises a small triangular surface of more or less inclination, called the "posterior spur triangle". The middle part of the spur connects these two surfaces with one another.

In the majority of the tracheæ studied, it is the plate of cartilage corresponding to the last tracheal ring, or a cartilaginous process of the last tracheal ring, which enters into the spur. In these cases the spur was designated as "cartilaginous-tracheal".

It was often difficult to determine whether bronchial cartilages or tracheal cartilages entered into the formation of the spur. The usual distinction of a spur as bronchial or tracheal was to recognize whether the respective cartilage rings lay above or below

per cent, partly membranous and partly cartilaginous in 11 per cent, in 21 per cent it was bronchial, divided as follows—15 per cent bronchial right, 3 per cent bronchial left, and 35 per cent double bronchial

The possibilities of compression are greater in those cases in which the tracheal rings are mechanically impaired.

Friedleben's studies in 1858 leaned largely toward the direct pressure theory and gave rise to the large controversial literature which exists to-day. That mechanical factors are concerned in some cases seems undeniable, but alone they by no means offer a wholly adequate or satisfactory solution, and the sudden arrest of the heart must be accounted for by some complex nervous-toxic mechanism which up to the p

Fig 14 Same case as shown in Figure 13,
lateral film Note tracheal compression

Fig 15 Same case as shown in Figure 13, six
weeks after treatment

has not been satisfactorily explained. The early pathologic findings of hyperthyroidism are equally mystifying, although varied therapeutic interferences are used with varying degrees of success, in spite of the inability to advance a rational explanation of the mechanism of cause and effect. This thesis so far is presented to orient the pressure theory.

It is appropriate to mention the physiologic functions advanced by different authorities:

(1) Thymectomy has no effect on growth and development of skeleton or organ

(2) Thymus feeding to salamander larvae, with parathyroid, causes tetanus

(3) Thymic hyperplasia in thyrotoxicosis is secondary

(4) In birds, a relationship exists between the thymus and the egg-laying mechanism

(5) One, if not the primary, function

of the thymus gland is to produce leukocytes

(6) The thymus may have antitoxic function

(7) Thymic death, not due to tracheostenosis, probably bears no relation to the state of the thymus gland

(8) Thymic hyperplasia in thyrotoxicosis is secondary

(9) A substance is contained in the thymus, which, when injected, causes convulsions

(10) Castration delays involution of the thymus

(11) The thymus is not necessary to life

It is known that the gland is a temporary or transitory organ of extra-uterine life, attaining its largest size at or soon after birth, and that it exists under three or four morphologic conditions.

We now enter the realm of roentgenology. Wasson, making serial roentgen-

ograms and serial physical examinations from birth to the age of three years, has made a thorough study of a group of chil-

dren. From roentgenologic and necropsy studies, he concluded that the two auricles and the great vessels form the base of the

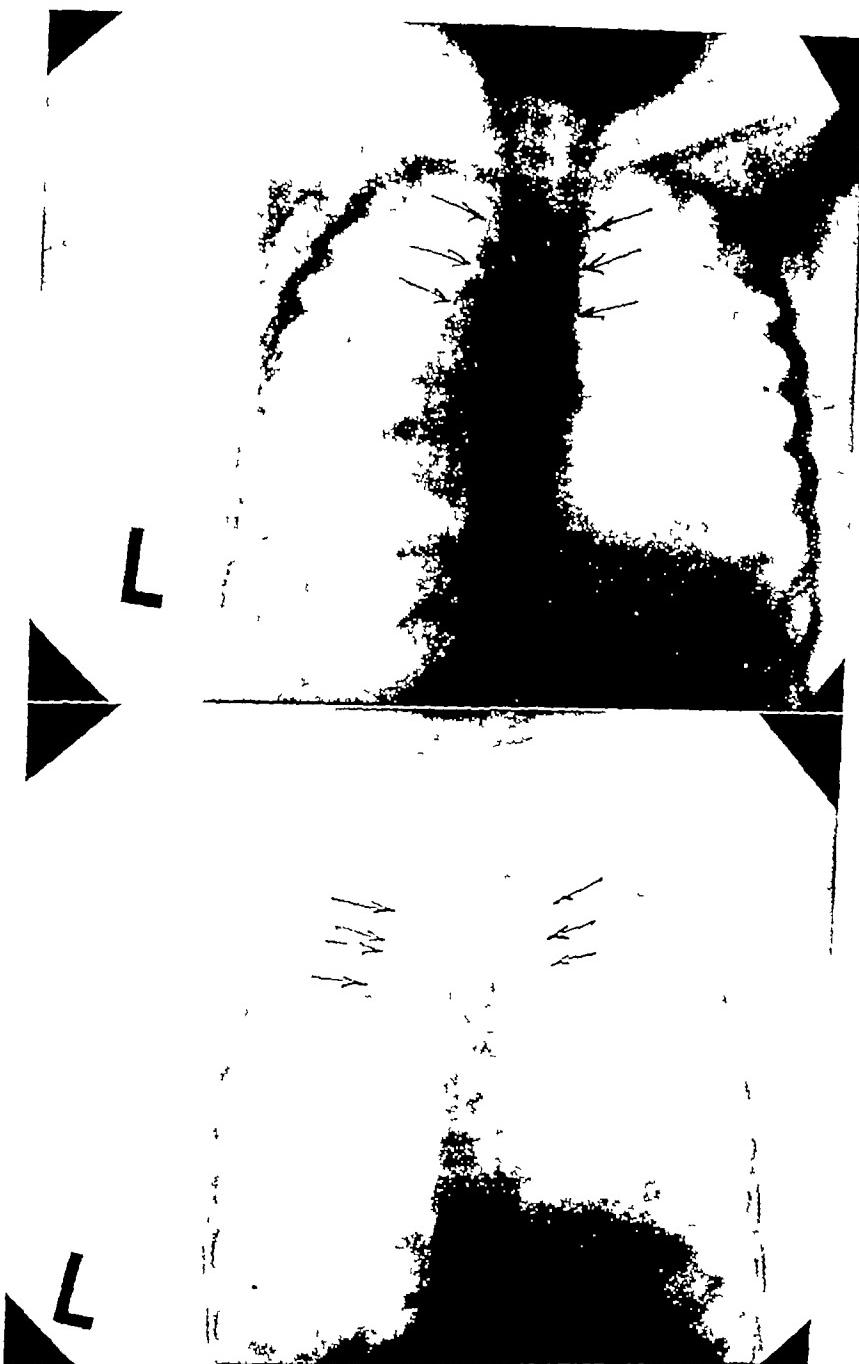

Fig. 16 (*upper*) Film after deep inspiration showing the mediastinal shadow. Compare with Figure 17, taken after deep expiration.

Fig. 17 (*lower*) Note transverse increase in mediastinal shadow, some of which is probably due to flattening or a large thymus. The thymus, in this instance, is increased in depth and manifest only after expiration.

heart shadow, the aorta, which lies in the middle of the mediastinum, in the new-born infant is not seen as a distinct shadow because of its position. It passes directly up, turns directly back, and passes down behind the heart, it is only in later life that it forms the typical aortic arch seen in adults.

If there is no sizable thymus present, the great vessels, the vena cava, aorta, and pulmonary artery, form a shadow, triangular in shape, which quickly narrows as it passes upward toward the first rib, and at its narrowest point is less than the transverse diameter of the shadow of the spinal column. If the thymus is considerably enlarged, it will be found to overlap the base of the heart, obscuring the shadow just described by the great vessels. The shadow of this thymus is triangular in shape, with its base overlapping the base of the heart and especially the auricles. Its transverse diameter at its broadest point, which is usually the third interspace, may be two or three times the diameter of the shadow cast by the thoracic spine. This shadow of the thoracic spine is taken by measuring the diameter of the vertebral body. If the shadow of the thymus is no greater than that cast by the great vessels, it is a small thymus. This applies only when the roentgenograms are taken in the postero-antero-recumbent position. The usual normal thymic shadow is about one and one-third times that of the vertebrae. Wasson concludes that, in infants under two years of age, the thymus is variable in size, not only in different types of infants, but in the same infant at different times. These thymuses may be classified as to size, and it is fairly definitely established that underweight infants have small thymuses, and those who are overweight have large thymuses. While the average-weight infant usually has a moderate sized thymus, this does not adhere so strictly to the rules. There is an increase in the thymus from birth to one year of age, it then reduces in size noticeably up to the

thirty-second month. Wasson calls this the thymic cycle.

Whenever possible, it is desirable to make a lateral projection in order to note a possible compression of the trachea, but, because of the infant's intractability, this cannot always be done. It is well to take a film after inspiration and another after expiration, however, infants are incapable of understanding co-operation and, therefore, ordinarily the examination must of necessity be limited. These films might show a comparative spread of the thymus, which is occasionally greatly increased if the thymus should be large in its anteroposterior dimension, the increase being shown in the film taken after expiration.

The question of a differential diagnosis is to be considered and the help of a pediatrician is of inestimable value. Confusion arises with the following simulants: congenital heart disease, meningitis, whooping cough, asthma, adenoids, congenital atelectasis, recurrent laryngeal paralysis, laryngeal stenosis, tracheal stenosis, retropharyngeal abscess, and foreign bodies.

The clinical evidences of thymic enlargement, such as transitory cyanosis, dyspnea, croupy cough, choking, and breath-holding, are common in these conditions, therefore care is necessary in the selection of remedial measures.

Lange, in 1911, made quite an exhaustive report on the roentgenologic treatment of enlarged thymus. Since then, X-ray treatment has been practised with apparently good results, as a matter of fact, no other form of satisfactory treatment has supplanted it. Singularly enough, because the structure is predominantly lymphatic, it is highly susceptible to light doses of X-ray.

Since it is always desirable to establish the safety of any therapeutics, Barnes, in 1929, made a study of 63 children who had received treatment from three and one-half to eight years previously, but he failed to demonstrate any constant deviation from

normal, either mental or physical. The dosages used, while somewhat high, in the light of our present knowledge, were apparently within the range of safety.

Treatment.—There is no need to apply larger doses than necessary and a certain amount of judgment in deciding the factors is desirable. In practically no instance is it necessary to give over one-quarter of an erythema dose at one time, usually one-sixth, or occasionally one-eighth, of an erythema dose may be indicated at one time. In the average case, three treatments are given, about two or three weeks apart. In this way involution is gradual and increased symptoms due to engorgement and toxemia are avoided. In rare instances, eight treatments are necessary. The writer had two instances in which an early X-ray examination, made as a precautionary measure, was negative, but several months later symptoms and re-examination revealed the presence of a large thymus. In both cases X-ray therapy abated the symptoms. These cases indicated that a latent or delayed pathologic thymus may exist.

The larger the thymus, usually the smaller the dose, also, the greater the evidences of inanition, the smaller the dose. While it is desirable to make repeated X-ray films at monthly intervals, the sole criterion is the evidence of improvement, which is remarkably obvious within from a few days to a few weeks.

The technical factors are 110 K V peak, 5 ma, + mm aluminum filtration, and two variables, namely, time and skin focal distance.

X-RAY TREATMENT IN GYNECOMASTIA

By JOHN G MENVILLE, M.D.

Surgical Pathological Laboratory, Department of Surgery,
Johns Hopkins Hospital and University,

BALTIMORE, MARYLAND

GYNECOMASTIA has been under discussion since the days of Aristotle (1) and many theories have been advanced concerning its causation. Up to the present time, however, none has proved satisfactory. Some of the most comprehensive early articles on this subject were written by Gruber (2), Laurent (3), Olphan (4), and Schuchardt (5).

Gynecomastia implies swelling of the male breast, which may be diffuse, local, unilateral, or bilateral. Clinically, gynecomastia may be divided into diffuse and local (fibro-adenoma) hypertrophies either may be unilateral or bilateral. Pathologically the local and the diffuse hyperplasias cannot be separated, for the early picture of hyperplasia gradually changes into fibro-adenoma. In other words, the young periductal fibroblastic tissue, present in early hyperplasia, gradually condenses and in time becomes a dense fibrous stroma which is typical of fibro-adenoma. This conclusion was reached after studying eighty-eight cases of gynecomastia, including a correlation of history, physical, laboratory findings, and a follow-up of the cases. The microscopic sections were compared to those of female breasts suffering from similar conditions. This study will be reported in another paper.

The first authentic report regarding treatment of swelling of the male breast was advanced in 1556 by Paulus Aegineta (7), who advised surgical removal. Since the majority of the cases are symptomless and complain only of deformity, treatment is seldom sought. However, the disfigurement has been responsible, in the case of some sensitive patients, for attempts at self-amputa-

tation, in an effort to be rid of the shameful swelling. Christopherson (8), in 1904, called attention to a boy who was so despondent over his affliction that he attempted self-mutilation. When seen, he had amputated one breast and, losing courage and strength, had only partially amputated the other breast. In 1837, Petrequin (9) reported a case in which the patient's mortification was the direct cause for amputation of both breasts. From the beginning of the nineteenth century it had not been uncommon to amputate one or both breasts for the deformity associated with gynecomastia.

In addition to deformity, pain is sometimes a complaint of gynecomasts, and although treatment for this symptom has not been as radical, patients have frequently subjected themselves to amputation in an effort to eliminate this sensation.

In 1922, Loederich and LeGoff (10) used radiotherapy in a 76-year-old patient suffering from an enlarged, tender, and painful breast. They reported a complete disappearance of pain, considerable decrease of tenderness, and a marked diminution in the size of the gland, following this treatment.

Because so little is known of the effect of X-ray treatment in gynecomastia and since such an excellent result was obtained in one of the author's cases, the following case reports are presented with the hope that they will bring to light another method of combating this clinical entity.

CASE REPORTS

Case 1. The patient was a white male, aged 12, who came to the hospital complaining of an enlarged right breast, which for the past few days had caused pain. In Sep-

Fig 1. Case 1. A white male 12 years of age showing a diffuse enlargement of the right breast of seven months' duration.

tember, 1922, he first noticed a gradual, diffuse, painless swelling, about three inches in diameter, of the right breast, which gave the sensation of fullness. Seven months later, and one week previous to examination, the patient traumatized his right breast while playing and this was followed by a diffuse "pin point discomfort" which lasted three days. Four days later, on April 19, 1923, the patient presented himself for examination (Fig 1). Previous to this the patient had not suffered from any sudden enlargement, disappearing tumefaction, or nipple discharge. No symptoms were noted in the left breast.

The past and family histories were essentially negative.

Physical examination showed a distinct, diffuse enlargement of the right breast, with

no visible lesions. Palpation revealed this enlargement to be free from the skin and the underlying tissues. There were no palpable masses and no enlargement of the axillary glands. The genitalia were normally developed for a boy of his age. The rest of the physical examination, including the left breast, was essentially negative.

Laboratory Examination—The X-ray examination showed no evidence of lung metastasis. The Wassermann test and complete blood examination were negative. A urinalysis revealed a specific gravity of 1.004, a trace of albumin, and an occasional pus cell. The blood pressure was 90/30.

Treatment—Three X-ray treatments were administered at intervals of two weeks. In each treatment the following procedure was adopted. Area over right breast, anteriorly, one-half hour, 175 K V, 5 ma., filter of 1 mm copper and 1 mm aluminum, 22-inch focal distance.

Progress Notes—Following each treatment a perceptible decrease in the size of the right breast was noted. This decrease in size was so marked after the third treatment that irradiation was discontinued. For the following four months the patient was seen once a month and each time the right breast was noticeably smaller. Four months after the last treatment the swelling had practically disappeared.

On October 26, 1931, eight and one-half years after the last X-ray treatment, the patient was examined by the author (Figs 2-A and 2-B). Since his last examination he has noticed no swelling nor has he felt any pain or discomfort. He had been entirely oblivious to his former affliction until recent communications reminded him of it. Physical examination at this time revealed the right breast to be identical with the normal left breast. No visible lesion, discharge, nipple retraction, or swelling was noted. Palpation revealed no glandular or soft part enlargement beneath the nipple.

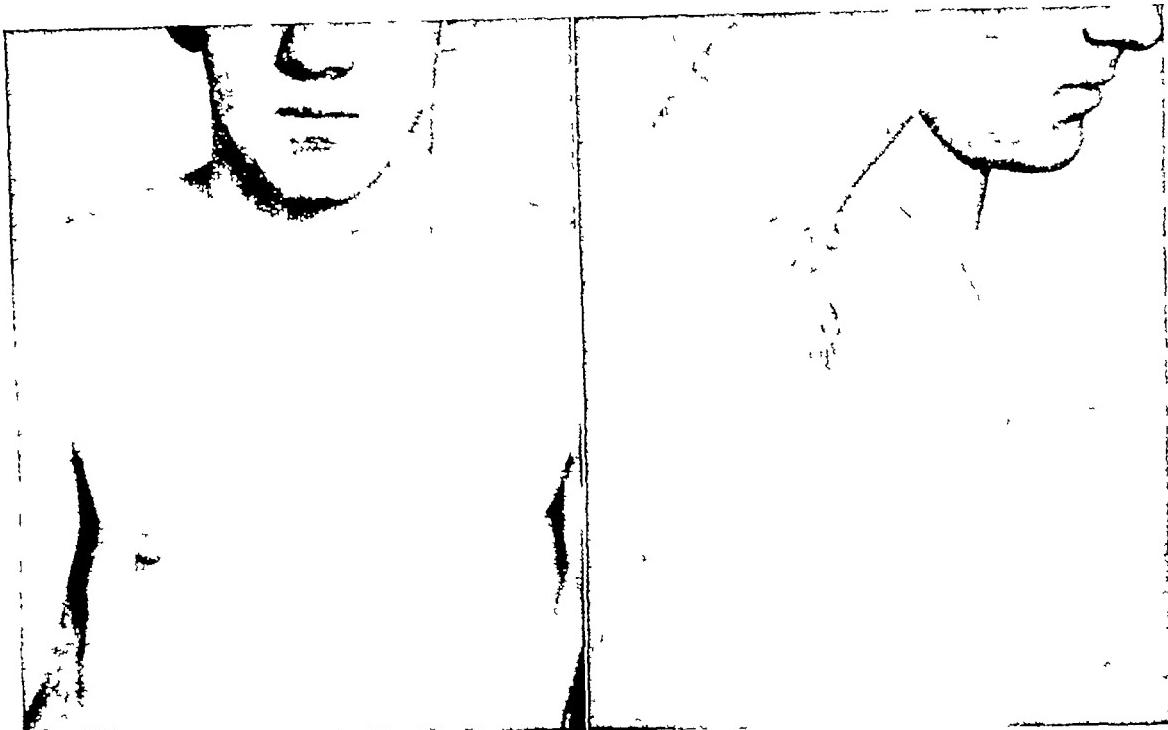

Fig 2-A Case 1 Anterior view of the patient shown in Fig 1, eight and one-half years after the last administration of irradiation by deep X-rays, showing an absence of gynecomastia

Fig 2-B Case 1 Lateral view of the patient shown in Figure 2-A

The remainder of the physical examination, including the genitalia, was essentially negative except for a beardless face and a moderately high pitched voice, neither of which is uncommon at 20 years of age

Case 2 The patient, a white male, 23 years of age, accidentally noted tenderness and a small mass about two centimeters in diameter, posterior to his left nipple. The mass for the first few months fluctuated in size and tenderness, but for the following two and one-half years there was a gradual increase in size, with no change in tenderness. Approximately three years after the onset nine treatments of deep X-ray were given on nine successive days, the total amount being similar to that used in Case 1. For the first three weeks following treatment the patient thought that there was an improvement in his condition. However, after the first month, the gradual growth

and constant tenderness were again noted. One year following X-ray treatment, the patient presented himself for examination. At that time inspection revealed a fullness of the left nipple. On palpation a firm, slightly tender, freely movable mass about five centimeters in diameter, posterior to the left nipple, was found.

Laboratory Examination—The X-ray examination was negative. The blood and urine examinations were negative.

Operation—A complete excision of the areola and glandular mass was performed.

Post-operative Findings—The patient made an uneventful recovery. To-day, eleven months later, this patient is living, with no recurrence of the tumor mass.

Gross Specimen—A circumscribed, bluish-white, firm mass posterior and inferior to the nipple, measuring $4 \times 3 \times 2$ centimeters was noted (Fig 3). Gross sec-

Fig 3 Case 2 Gross specimen of unilateral gynecomastia in a white male 23 years of age, showing a mass, posterior and inferior to the nipple, which had been present for three years. This breast had received irradiation for a nine-day period.

tion (Fig 4) revealed dense fibrous striations through which bluish-white tissue projected. Occasional yellow opacities were also seen.

Microscopic Section—The tissue revealed

Fig 4 Case 2 Cross-section of specimen shown in Figure 3, showing dense fibrous striations through which bluish-white tissue projects

a mild hyperplasia of the duct parenchyma, with a slight tendency toward cell atrophy (Fig 5). In areas, slight desquamation into the duct lumen was present. The periductal as well as the interductal fibrous stroma was dense, being composed of adult and well formed fibroblasts. In the periductal stroma

Fig 5 Case 2 Microscopic section of the specimen shown in Figure 3. It presents an adult fibrous periductal stroma and a slight atrophy of the hyperplastic duct epithelium.

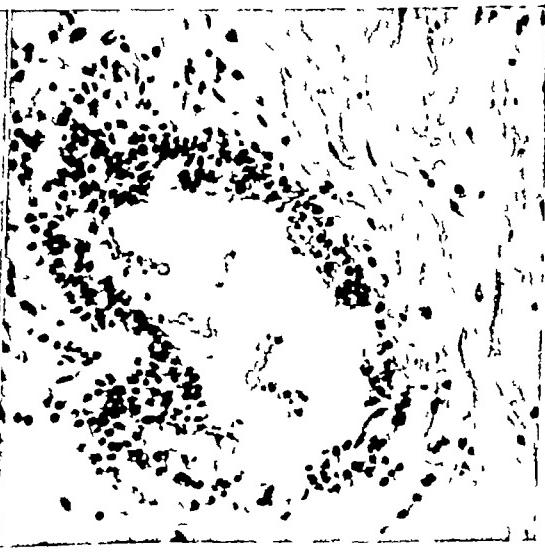

Fig 6 Case 4 Microscopic section of a white male 44 years of age showing atrophy, desquamation, and breaking up of the parenchymal cells lining the duct lumen. The breast of this patient received irradiation by deep X-rays (Compare with Figure 7)

Fig 7 Microscopic section of a normal, non-irradiated breast taken from a 65-year-old male showing desquamation, atrophy, and a breaking up of the parenchymal cells lining the duct lumen

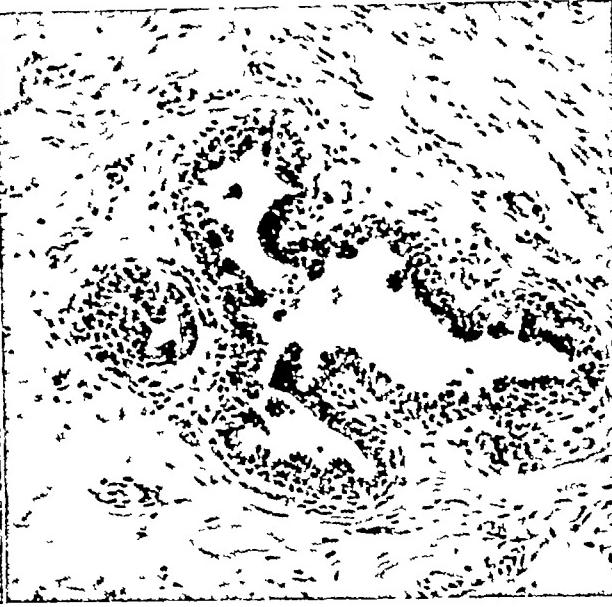

Fig 8 Microscopic picture of gynecomastia occurring in a white male 17 years of age, showing hyperplasia of intact parenchymal cells lining the duct lumen and surrounded by a dense fibrous stroma. This case was not irradiated and is shown only for comparison (See Figures 6 and 7)

mild lymphocytic infiltration was occasionally seen

Case 3 Six weeks previous to examination the patient first noticed a "small lump" in his right breast and a needlelike pain, originating in his right nipple whenever it was touched. No improvement was noted. Four weeks later, he was given one deep X-ray treatment by his physician.

Physical examination revealed a poorly developed, white male, 67 years of age. The right areola was slightly more prominent than the left. On palpation a circumscribed, freely movable, slightly tender mass about five millimeters in diameter, in the upper outer quadrant of the right breast, was noted. The remainder of the physical examination was negative.

Laboratory Examination—The X-ray examination was negative. Both the blood and urine examinations were negative.

Operation—The areola and tumor mass were completely excised.

Result—The patient died fifteen months later from "bladder inflammation."

The gross and microscopic sections are similar to those of Case 2.

Case 4 Four months previous to examination the patient noted tenderness and a small "lump" below his right nipple, both of which gradually increased for three months. At the end of this time, he was given X-ray treatment by his physician, but the tenderness and swelling persisted.

Physical examination revealed a white male, age 44. The right nipple was slightly higher than the left.

On palpation a flat, definite, indurated mass about two centimeters in diameter was found, attached to the nipple but not to the underlying structures. The remainder of the physical examination was negative.

Operation—The right breast was amputated.

The gross specimen presented a firm, fibrous, tumor mass, posterior to a normal

nipple, with ill-defined edges measuring from one and a half to two centimeters

The microscopic section showed a duct hyperplasia with desquamated cells in its lumen and an apparent atrophy of the parenchymal cells (Fig 6) The stroma was dense and fibrous and contained a slight lymphoid infiltration in its periductal bed

Result—The patient could not be located five years later

DISCUSSION

In an effort to explain the result of X-ray treatment in gynecomastia one must first realize the presence of a hyperplasia of the parenchymal cells, together with a hyperplasia of the periductal, loose, young, connective tissue stroma in this condition This type of stroma is frequently seen in gynecomastia of short duration Irradiation seems to have a specific retarding effect on the growth of this young connective tissue element, as well as a tendency to produce atrophy of the parenchymal cells If the hypertrophy is maintained for a longer period of time, the young fibrous tissue condenses and becomes more mature X-ray treatment does not seem to have any effect on the maturing or matured fibrous hyperplasia

In Case 2 the mature fibrous element had already formed when X-ray treatment was given, consequently the total effect produced seemed to be a slight atrophy of the parenchyma

In Cases 3 and 4 the amount of X-ray treatment given is not known The lapse of time between treatment and operation was too limited to justify a conclusion that the results were poor However, the microscopic picture in both cases offers an explanation by presenting an adult stroma and an atrophy of the parenchymal duct cells

TREATMENT

In all probability the first treatment used in tumefaction of the male breast was rest

and advice not to manipulate the part This was the natural result of the limited knowledge of gynecomastia that prevailed at the time

Up to the present time, the accepted treatment for cases of gynecomastia has been to leave them alone If pain is not relieved by suggestive and palliative measures, and if the deformity is a constant source of mental anxiety, amputation is considered

In view of the findings recorded, X-ray irradiation should be resorted to in all cases of gynecomastia of short duration Best results seem to be obtained in the diffuse enlargements in cases in which the young periductal fibrous tissue is in abundance After X-ray treatment has been given a fair trial, if the results are found to be unsatisfactory a more radical procedure is to be considered Deaver and McFarland (11) are of the opinion that amputation of the breast or breasts, affords the only lasting benefit in gynecomastia

CONCLUSIONS

- 1 Gynecomastia may be local, diffuse, unilateral, or bilateral
- 2 The hyperplasia of gynecomastia gradually changes into the so-called fibroadenoma
- 3 The early hyperplasia in gynecomastia seems to be sensitive to X-ray irradiation

Way Nerves Act on Muscles Discovered—The mechanism by which a nerve impulse can be converted into a chemical stimulus has been indicated in studies reported by Prof Walter B Cannon, of Harvard Medical School, to the Association for the Study of Internal Secretion Prof Cannon described his newly discovered hormone, sympathin, which is found very generally in smooth muscle tissue It is probably the same as

adrenalin, the stimulating secretion of part of the adrenal glands The action of the two substances—sympathin and adrenalin—is apparently very similar

The discovery of sympathin is expected to have great practical importance Secretion of sympathin from a muscle cell upon stimulation by a nervous impulse may be the way in which the nerve impulse can cause activity of tissue—*Science Service*

DIRECT COMPUTATION OF DEPTH INTENSITY

By KENNETH S COLE, PH.D., Department of Physiology, Columbia University, and
Roentgen-ray Department, Presbyterian Hospital, NEW YORK

IN DEEP therapy, sufficient radiation should be absorbed by the tissue under treatment to give the desired effect without there being enough radiation absorbed at the skin to produce a severe reaction. If treatments are to be put on a quantitative basis, it is then necessary to know the amounts of radiation absorbed—preferably expressed in r units—at both skin and depth, so that the clinician may learn by experience what quantities are necessary to produce reactions at the skin and in various tumors. Thus it is important to be able to compute the depth intensity simply and easily.

Most, if not all, published phantom measurements give intensities of radiation relative to the intensity at some point in the phantom. This point is usually at the surface for some arbitrary area of field. If we then wish to use these measurements to find the intensity at a certain depth, we must measure the intensity for at least one point in a phantom. Since water phantom measurements are inconvenient at the best, it seemed expedient to make them once and for all in terms of the intensity of the radiation as measured in air without back-scattering at the skin-target distance.

The X-ray tube was operated at 200 KV,

TABLE I

| Filter 1 mm Al + mm Cu | Intensity r/min |
|------------------------------|--------------------|
| 0.55 | 22.2 |
| 1.1 | 14.6 |
| 1.86 | 9.6 |
| 2.62 | 6.6 |

8 ma constant potential. At 50 cm it gave the copper filtration intensity data of Table I, without back-scatter. Table II gives the percentages of the intensity in air which are found for different depths, fields, and filters. The very striking result is that, for any given filter, field, and depth, the phantom intensity is always a constant percentage of the air intensity for the same filter—no matter if it be 0.55 mm or 2.62 millimeters. For convenience this percentage is called the phantom factor or ratio. In Table III the data from Table II at 10 cm depth and different fields are compared with those of Failla and Quimby (Table XVI and Figure 8).¹ The agreement is good enough to justify the use of Failla and Quimby's data in computing the phantom factor for different fields at the other depths from the

¹G. Failla and E. H. Quimby, Am. Jour. Roentgenol. and Rad. Ther., December 1923, p. 944-967.

depth data with 225 sq cm field. These results are given in Figure 1.

0.55 mm and 2.62 mm copper. Conversely, this phantom factor should be independent

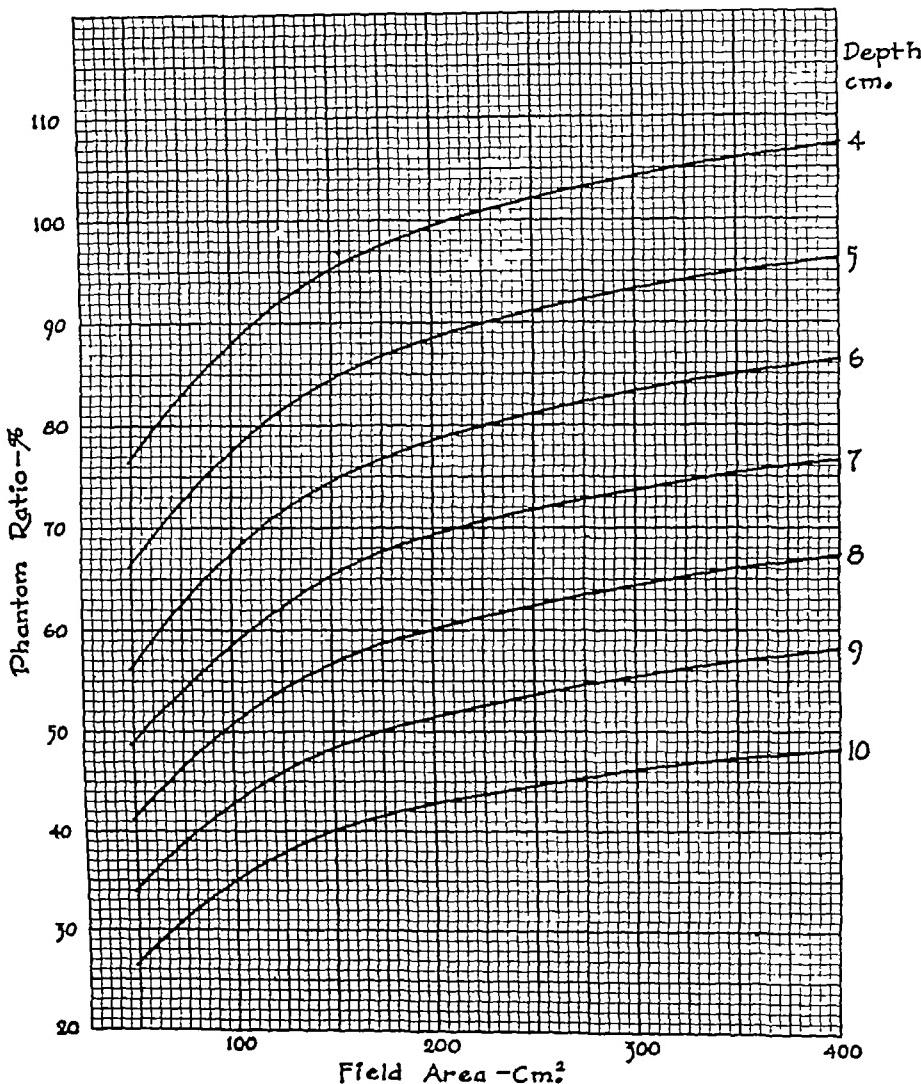

Fig. 1

The set of curves shown in Figure 1 make it surprisingly simple to compute the amount of radiation absorbed by any underlying tissue. Let us suppose that 600 r (measured in air) have been given over a skin area of 144 sq cm with 50 cm skin-target distance. We then know immediately that a tissue at a depth of 5 cm has absorbed 500 r since this phantom factor is 84 per cent from Figure 1. This result is the same when the 600 r is given with any filtration between

of the tube voltage for at least a limited range. This points to the interesting suggestion that the use of high voltage and heavy filtration is of slight value in giving

TABLE III

| Field | Table II | F-Q | Ratio |
|-------|----------|------|-------|
| 400 | 486 | 1.38 | 352 |
| 225 | 436 | 1.25 | 348 |
| 100 | 353 | 1.00 | 353 |
| 48 | .266 | 0.78 | 341 |

greater depth intensity. Suppose it is known in advance that a region 10 cm deep should have 350 r through a 315 sq cm field. From Figure 1 the phantom factor is 46.5 per cent, so 750 r (measured in air) must be given. It now remains to choose such filter and voltage that 750 r will not produce a skin reaction on the 315 sq cm field. Filter and voltage are the factors to be adjusted to protect the skin after the quantity of radiation (as measured in air) necessary to produce the desired depth intensity is known.

from clinical experience and the phantom factor.

Further measurements are planned to set the limits of voltage and filter on the phantom factor, to check the application of Failla and Quimby's inverse square relation to the phantom factor at other S.T.D., and to find the minimum depth at which the phantom factors may be used. It is obvious that their independence of wave length must fail at and near the surface since the usual depth dose is not independent of wave length.

List of All Science Journals being Compiled in England—British scientists are now listing all the periodicals of science. A new edition of the "World List of Scientific

Periodicals," the first edition of which contained titles of some 24,000 periodicals, is to be issued soon. The editor is W. A. Smith of the British Museum—*Science Service*.

SYSTEMIC BLASTOMYCOSIS, WITH REPORT OF A FATAL CASE

By ISTVÁN GASPAR, M.D., WALTER A. FENSTERMACHER, M.D., and
LESLIE R. LINGEMAN, M.D.

From the Rochester General Hospital, ROCHESTER, NEW YORK

CASES of systemic blastomycosis, though the disease is fairly widespread, are still not very common. In spite of the excellent reviews on the subject and the many cases of systemic blastomycosis which have been reported in the various medical journals, it seems to us that our case, studied from clinical, roentgenologic, bacteriologic, and histopathologic points of view, warrants its publication.

At the Rochester General Hospital two cases of systemic blastomycosis have been seen within the last three years. The first one, in which a hen's-egg-sized tumor of the leptomeninges was removed from a 52-year-old white male, was a so-called primary meningeal form and has been reported elsewhere. The tumor showed a great number of budding organisms and a characteristic microscopic picture; however, the case was not entirely conclusive because only histologic examination was done. Cultures could not be prepared and autopsy was not obtained. The second case of systemic blastomycosis with multiple foci was observed during 1930. At the time of the patient's admission only a few lesions were found, nevertheless the correct diagnosis was established in a few weeks, thus determining the available treatment and the poor prognosis. The case is as follows:

CASE REPORT

C. P., male, Italian parentage, aged 19 years, entered the hospital Feb. 22, 1930, with the following chief complaints: (1) sores on right foot and right wrist; (2) swellings of knees; (3) weakness. The family history was irrelevant.

Past History.—The patient was born in, and has always lived in, New York State. He was in the Rochester State Hospital from Sept. 30, 1928, to April 26, 1929, with the diagnosis of dementia praecox. No history of past diseases or symptoms was obtained on searching inquiry. He had been unemployed for some time, though he had previously worked in a grocery store. Most of the history of his present illness was obtained from the family, who had considered the patient physically well until December, 1929. During that month, after a slight trauma, the patient noticed a sore on the right foot, with accompanying fever. The lesion was incised and "pus" obtained; however, drainage of the thin fluid was continuous. The right, and later the left, knee became swollen and painful. Swellings and later ulcerations of the right ankle and right wrist were noted. Fever of varying degrees had been present since the beginning of the illness. Progressive weakness and a loss of ten pounds were experienced. There had been an occasional cough and on one or two occasions a small amount of blood-tinged sputum was expectorated. No gastro-intestinal or genito-urinary symptoms were present. There was no change in the mental state.

Physical Examination.—Physical examination revealed that the patient was well developed, but poorly nourished, with an appearance of chronic illness. The skin was yellow, with numerous acneform lesions over the face and chest, and the general hygiene was poor. The patient possessed a grinning face, and talked in a foolish way, giving irrelevant answers. He was dull, uninterested, and unable to discuss his condition.

Examination of the eyes showed that the right pupil was larger than the left, both reacted sluggishly to light and accommodation. The fundi were negative.

Throat and mouth Considerable post-

Heart Blood pressure, 120/80. The apex was at the fifth intercostal space, 10 cm to the left of the midsternal line. Rhythm was regular and there were no murmurs.

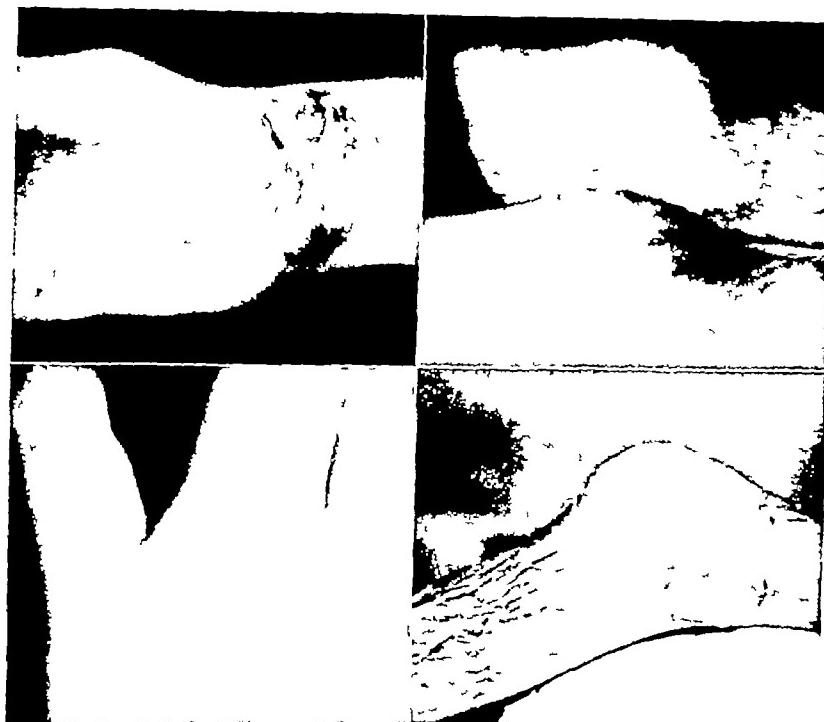

Fig 1 (upper left) Two pigmented swellings of the flexor surface of the right wrist. One of the swellings has already become ulcerated.

Fig 2 (upper right) Swelling of the knees during the first months of involvement of the knee joints.

Fig 3 (lower left) A pigmented swelling over the first metacarpal bone of the left fourth finger which later became ulcerated.

Fig 4 (lower right) The left knee joint denuded of the covering skin during the latter part of the disease.

nasal discharge was present. The tonsils were enlarged and very cryptic. One or two carious teeth were present. The tongue was white-coated and dry.

Chest The expansion was fair, but the right chest lagged on inspiration.

Lungs On the right there was relative dullness over the first, second, and third intercostal spaces anteriorly and posteriorly, with diminution in breath sounds anteriorly. The voice sounds were slightly increased. No râles were heard.

Abdomen The spleen was palpable.

Extremities On the dorsum of the right hand there was a large, brownish-blue, pigmented area with two ulcers showing well defined borders, from these came a sero-sanguineous fluid. Anterior to the wrist were two pigmented fluctuant swellings (Fig 1). Over the dorsum of the right foot there were two irregular ulcers 3 cm in diameter, the skin about these areas being pigmented and the same thin fluid being present. There were two small swellings

Fig 5 Abscesses on the scalp

about the external malleolus. Both knees presented moderate effusion, but no discolorations were noted (Fig 2)

Laboratory Studies—The admission blood count was red blood cells 4,160,000, white blood cells, 11,000, hemoglobin, 80 per cent (Sahli). These lowered slowly until the last count showed red blood cells, 2,600,000, white blood cells, 7,800, hemoglobin, 40 per cent (Sahli).

Smears Neutrophils 80, eosinophils 2, large lymphocytes 1, small lymphocytes 17 per cent. The bleeding time was two minutes, clotting time, three minutes. The blood Wassermann test was negative. The urine occasionally showed a 1+ albumin and a few white blood cells.

Progress—The patient was in the hospital seven months, during which time there was a slow but steady progression of the disease with little tendency to remission. There was a gradual loss in strength, appetite, and weight, until a state of extreme emaciation was reached. The patient complained of headaches and joint pains. His temperature remained above normal during the entire course and during later stages reached 104° F or more. At times a systolic murmur was heard at the base of the heart. The mental status remained unchanged until the later weeks, when he developed delusions of fear.

Locally, lesions developed in succession on the left ankle, left hand (Fig 3), lower back, right forearm, left wrist, knees (Fig 4), over the sternum, upper back, scalp (Fig 5), etc., until the patient was literally riddled with them. It was characteristic that at first a fluctuant swelling appeared which later became pigmented and ruptured unless incised (practically all were). These lesions then continued to drain the serosanguineous fluid which was released. Coincident with each early swelling, X-ray examination always showed typical bony change with rupture of the periosteum, and subcutaneous tissue and skin manifestations. As each individual lesion progressed in size, the skin seemed to "melt" away, leaving large denuded areas.

The treatment consisted of general supportive measures with sedatives and palliatives. Local lesions were widely incised as soon as the first swellings were noted. The knees were aspirated. Wet dressings of 1 per cent copper sulphate and acriflavine were used, and large doses of potassium iodide were given orally and intravenously. Early in the illness one transfusion was given. Weekly neo-arsphenamine was tried. A vaccine was made, but in view of the patient's poor condition it was not administered. X-ray therapy was considered, but in view of the extensiveness of the process, it was considered futile.

ROENTGEN-RAY FINDINGS

At different intervals, X-ray films were made of every bone of the body, but the observed lesions showed no predilection for any part of the skeleton. They were purely destructive throughout the course of the disease and were characterized by the lack of reparative and of periosteal reaction, clear-cut margins, their location in the cortex, lack of osteoporosis, their multiplicity, rapid development, and accompanying sinuses.

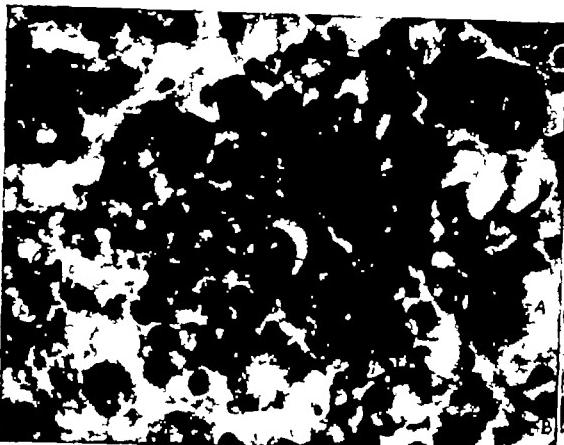

Fig. 6. A larger blastomycete (*A*) is being attacked by leukocytes (*B*)

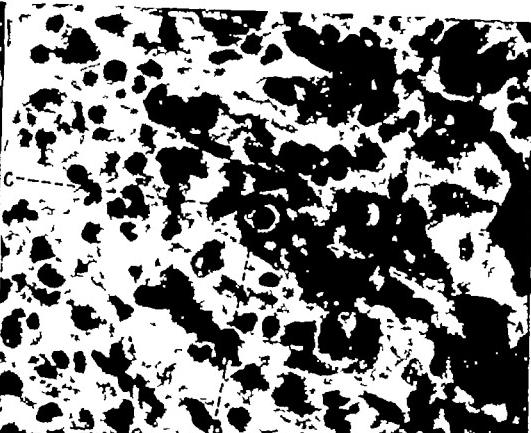

Fig. 7. A smaller budding organism (*A*) is engulfed by a mononuclear phagocytic cell (*B*). One or two other phagocytic cells (*C*) have joined very closely

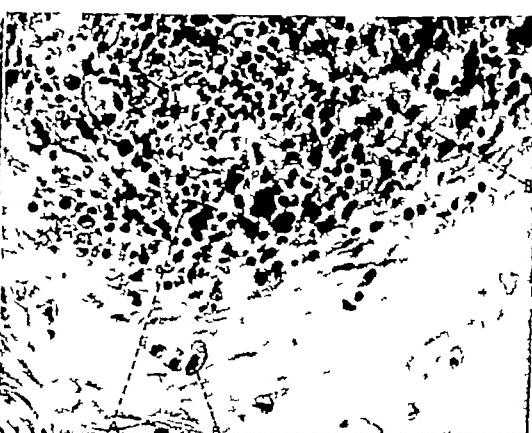

Fig. 9. The edge of an early lesion. Collection of leukocytes (*A*) and large mononuclear cells (*B*)

Lesions developed in the following bones multiple lesions of the bones of the vault of the skull (Fig. 13) involving both tables, the right acromion process, medial ends of both clavicles and the manubrium, condyles of the right humerus, upper end and shaft of the right ulna (Fig. 14), styloid process of the right radius (Fig. 15), the lower end and condyles of the left humerus, styloid process of the left radius, the crests of the iliae, the right greater trochanter, middle third of the left femur (Fig. 16), lower

third of the right femur, upper poles of both patellæ, right tibial tuberosity, right medial malleolus, distal ends of both first metatarsals (Fig. 17), and a marginal lesion of the eighth right rib.

In addition to the bone lesions, films of the chest at the time of admission revealed a consolidation of the right upper lobe which had the appearance of lobar pneumonia in an early stage of resolution. This lesion gradually cleared, until the last examination, made shortly before death, showed only a

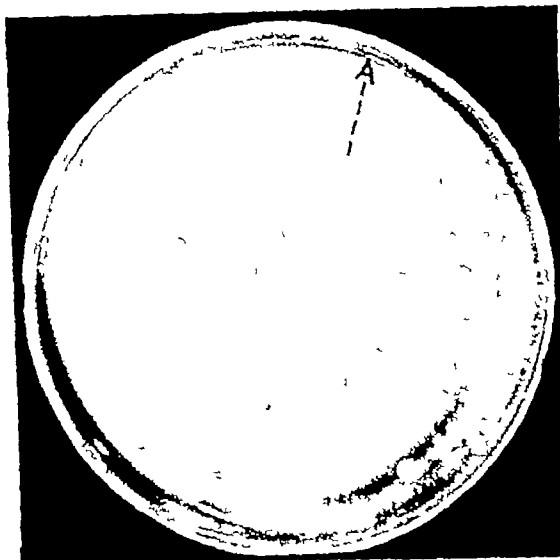

Fig 10. The colonies of the blastomycetes (*A*) on 2 per cent glucose agar

few lines of increased density radiating from the right hilum

BIOPSY

Soon after the patient's admission to the hospital, microscopic examination was done on a biopsy specimen which was obtained from a lesion which was just beginning to break through the skin from below, although the epidermis was still intact. In the corium and the subcutaneous connective tissue there was a lesion composed of numerous dilated blood vessels, delivering abundant polymorphonuclear leukocytes, furthermore hemorrhages, plump mononuclear cells with large, often foamy protoplasm and scattered masses of leukocytes, were disclosed. Blastomycetes, *viz.*, round bodies with highly refractive capsules, were disseminated throughout in moderate number. Their size varied a great deal up to 35μ in diameter. The large blastomycetes were usually attacked by leukocytes (Fig 6), while the small forms were taken up into mononuclear phagocytic cells (Fig 7). Other large phagocytic cells often joined to such a cell and, evidently, by their fusion the

foreign body giant cells developed (Fig 8). Such giant cells were found in a moderate number in this early lesion. Mitotic figures were observed in endothelial cells of blood vessels and in the mononuclear phagocytic cells outside of the vessels. Numerous phagocytic cells were packed with brown pigment granules which gave the iron reaction. This early lesion was not demarcated by a fibrous zone, the edge showing dilated vessels with numerous leukocytes and a gathering of large mononuclear cells in the tissue spaces (Fig 9).

Examination of a piece of the left iliac bone, removed at operation for an abscess of this region, showed that the bone abscess was walled off by a thin fibrous tissue containing abundant blastomycetes. The organisms were attacked by leukocytes, and minute abscesses were formed in the fibrous tissue. The neighboring bone marrow presented an accumulation of plasma cells and polymorphonuclear leukocytes, but no other remarkable changes. Pieces of bones removed at autopsy from bone lesions showed a similar picture.

BACTERIOLOGIC EXAMINATION

The first cultures were made on March 5 on Sabouraud's media and glucose agar from the open lesions on the right wrist. The colonies of blastomycetes appeared in from two to six days as pin-point sized, round, elevated, grayish spots soon showing radiating filaments. Some colonies were round for several days, bulging very much, firmly adherent, grayish, and only later on developing radiating filaments. As the colonies became older, they grew much larger, becoming one centimeter or more in diameter, and a great number of aerial hyphae developed, causing a fluffy appearance. The center of the colonies remained prominent (Fig 10). In glucose broth the growth was sluggish and fermentation was not obtained.

Microscopically the young colonies pre-

sented numerous septate mycelial filaments with true branching. The filaments showed granules. Round bodies could be found but they were scarce (Fig 11). In old, drying cultures the round bodies with refractile

organisms, but lesions could not be detected in any of the organs.

According to the above description, the isolated strain of blastomycetes belongs to the non-fermenting type described by Gilchrist

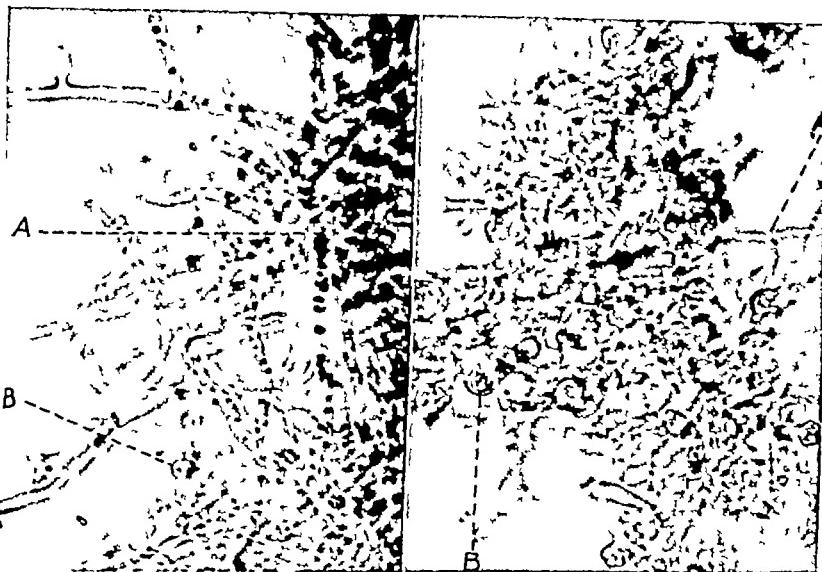

Fig 11 (*left*) Microscopic appearance of young colonies of blastomycetes. Numerous septate mycelial filaments (*A*) with true branching. There are only occasional round organisms (*B*).

Fig 12 (*right*) Older colonies under the microscope. There are mycelial filaments (*A*), but the round bodies (*B*) are abundant.

capsules were abundant (Fig 12). These drying cultures lost their fluffy character and appeared as velvety white colonies on glucose agar media.

Positive cultures were also obtained from the biopsy specimen and later on from a hip abscess and knee joint fluid. The peculiar brownish-red color and stringy consistency of the pus were noted. According to the histologic examination, the chocolate-brown color of the pus was due to the pigment found in the phagocytic cells. Cultures of blood, spinal fluid, sputum, urine, and feces were repeatedly negative for blastomycetes. The patient raised only a small amount of sputum.

A white mouse and a rabbit were injected subcutaneously and intravenously with a single dose of the emulsified colonies of the

(4) Castellani and Chalmers (2) classify these organisms under the name "odium."

POSTMORTEM EXAMINATION

An autopsy was performed a few hours after the patient's death on Sept 18, 1930 with the following findings. The skin of the extremely emaciated young man was pale and wrinkled and there were many ulcers covered with slough and a greenish discharge. A number of these were located on the scalp. An ulcer was located at the sternal end of the left clavicle and a sinus led from the bone to the surface. There were ulcerated areas over both knees, at the basis of which sinuses opened into the knee joints. The right knee showed two sinuses one on each side of the patella, the left knee

Fig 13. X-ray film of skull cap showing multiple lesions which involve both tables

one, on the outer side. The left wrist was ulcerated, especially over the distal end of the ulna, which was denuded of almost all soft-tissue covering except the extensor carpi ulnaris tendon that held it in place. Finally, there was a large ulcer over the sacrum.

The skull cap was perforated by two sinuses, and extensively eroded by a localized necrotic process which attacked the bone from both internal and external surfaces. In the left frontal region, a walnut-sized, extradural abscess was formed. The brain showed a corresponding depression. While the leptomeninges were thin, the brain itself showed no remarkable pathology on the surface or on the numerous frontal sections.

The inner surface of the manubrium sterni was carious, the discharge from this area being carried to the sinus at the sternal end of the left clavicle. The heart showed marked loss of epicardial fat, but otherwise the findings here were negative. The left pleura was smooth and glistening except an area 4 by 10 cm posterior to the lung root

where the left lung was adherent to the chest wall. Here the left lung was red but still crepitant. On cut section an increased amount of bloody fluid was expressed from this region. There was a small retropleural abscess due to a carious rib at this site. Another abscess was found, more lateral, and on a lower rib. The right pleura was smooth and the right lung was crepitant throughout, but its lower lobe was somewhat edematous. The fifth lumbar and the first sacral vertebrae were carious. The discharge drained posteriorly through a sinus described above.

Histologic examination of autopsy specimens showed areas of peribronchial fibrosis in the upper lobe of the right lung and atrophy, together with passive congestion of the liver. The other organs were not remarkable, except for the anemia and general atrophy. The lymph nodes were negative.

DISCUSSION

Systemic blastomycosis has presented lung lesions in about 90 per cent of the cases and, according to Stober (7), the pathology of the lungs consisted of old bronchopneumonic lesions. In our case X-ray examination of the lung showed a definite shadow which gradually cleared up. Sections of the lung from that region showed fibrosis of the peribronchial tissues and also of the alveolar wall, although no blastomycetes could be found. On the basis of these lung findings and in the absence of other convincing primary foci, we must also assume that probably the lung was the portal of entry of the blastomycetes.

Histologic observation showed that the blastomycetes were not digested either by the leukocytes or by the large phagocytic and the giant cells. It seems probable that the phagocytic cells, having engulfed the organisms would enter the blood stream and

sented numerous septate mycelial filaments with true branching. The filaments showed granules. Round bodies could be found but they were scarce (Fig 11). In old, drying cultures the round bodies with refractile

organisms, but lesions could not be detected in any of the organs.

According to the above description, the isolated strain of blastomycetes belongs to the non-fermenting type described by Gilchrist

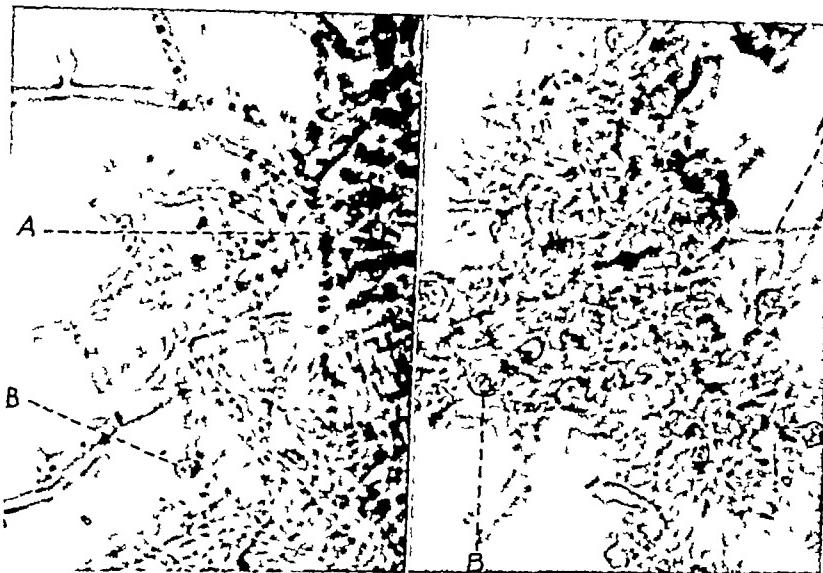

Fig 11 (left) Microscopic appearance of young colonies of blastomycetes. Numerous septate mycelial filaments (A) with true branching. There are only occasional round organisms (B).

Fig 12 (right) Older colonies under the microscope. There are mycelial filaments (A), but the round bodies (B) are abundant.

capsules were abundant (Fig 12). These drying cultures lost their fluffy character and appeared as velvety white colonies on glucose agar media.

Positive cultures were also obtained from the biopsy specimen and later on from a hip abscess and knee joint fluid. The peculiar brownish-red color and stringy consistency of the pus were noted. According to the histologic examination, the chocolate-brown color of the pus was due to the pigment found in the phagocytic cells. Cultures of blood, spinal fluid, sputum, urine, and feces were repeatedly negative for blastomycetes. The patient raised only a small amount of sputum.

A white mouse and a rabbit were injected subcutaneously and intravenously with a single dose of the emulsified colonies of the

(4) Castellani and Chalmers (2) classify these organisms under the name "oidium."

POSTMORTEM EXAMINATION

An autopsy was performed a few hours after the patient's death on Sept 18, 1930 with the following findings. The skin of the extremely emaciated young man was pale and wrinkled and there were many ulcers, covered with slough and a greenish discharge. A number of these were located on the scalp. An ulcer was located at the sternal end of the left clavicle and a sinus led from the bone to the surface. There were ulcerated areas over both knees, at the basis of which sinuses opened into the knee joints. The right knee showed two sinuses one on each side of the patella, the left knee

Fig 18. Chest on admission, the lesion occupying the right upper lobe. The lines of increased density seem to radiate from the hilum and are apparently due to a peribronchial infiltration

Fig 19. Film made shortly before death. The lesion of the right upper lobe has practically disappeared

it seems also probable that the re-infection of the system from a bone lesion may occur and other foci may subsequently develop if demarcation by fibrosis is inadequate. Such a process occurred evidently in our case, for the new lesions appeared at intervals of several weeks. A cutaneous lesion cannot be considered as the primary focus of the infection because it is always associated with bone lesions from which the deeper tissues and the skin became involved. Brain lesions were not found at autopsy, though a few cases have been published in which cerebral and cerebellar abscesses are reported (5). In our case only an extradural abscess was observed as a result of a skull lesion.

Bacteriologic examination of the biopsy specimen and the pus obtained at operations gave positive results. The blastomycetes grew readily on 2 per cent glucose agar plates at room temperature and were usually associated with *Staphylococcus aureus*. The

latter was considered as a secondary invader and not as a contaminating organism. Other observers have also found various organisms as secondary invaders (8). The blastomycetes cultivated from the various lesions always showed the same type of growth. The colonies were white and fluffy, due to the abundant aerial hyphae as long as there was enough moisture in the culture media. As the culture media became rather dry, the aerial hyphae disappeared, and the colonies turned velvety with a slight light brown hue. These colonies showed only round bodies under the microscope.

Histologically the lesions were different from those caused by the tubercle bacilli. It is not our purpose to consider in detail the histologic characteristics of the blastomycotic lesions. The microscopic picture and the features distinguishing it from tuberculosis were emphasized among other authors by one of us (3) in an article reported else-

Fig. 14 (*upper left*) Showing lesions of shaft and condyles of the humerus

Fig. 15 (*upper right*) Right forearm showing lesions in the ulna and the styloid process of the radius

Fig. 16 (*lower left*) Showing lesions in the shafts of the femora and the greater trochanter of the right femur

Fig. 17 (*lower right*) Antero-posterior film of feet with lesions in the first metatarsals Note the absence of bone production in all the bone lesions

the lung would clear up, the remainder being but a slight fibrosis. The living organism would have ample time to multiply if lodged somewhere, especially in the bones. The

epiphyseal portions of the bones and the cancellous bone tissue appear to be favorable places for the phagocytized organisms to be easily caught up and retained. Furthermore,

multiple bone lesions which later involved the soft tissues above the bone and ulcers of different sizes developed

3 Blastomycetes were found in the lesions culturally and histologically. The diagnosis of systemic blastomycosis was established after a few weeks of hospitalization of the patient.

4 Characteristics of the isolated strain of blastomycetes and the histology of the early lesions are described.

5 X-ray appearances of the bone lesions are given and the possibility of differentiating blastomycosis and coccidioidal granuloma from other bone lesions is considered.

6 The primary focus of infection was considered to be in the right lung. This consideration was supported by X-ray findings, though toward the end of the patient's life the lung cleared and blastomycetes could not be detected in sections of the lung

7 The various forms of treatment were unsuccessful

New Camera Records Stages of Ear Disease—The interior of the human ear can now be photographed with a new camera developed by Dr Richard Millar, director of the photography division of the Methodist Hospital of Indianapolis. The ear camera is hailed by the medical world as a distinct step forward in the treatment of ear diseases. For the first time in medical history a pictorial record of different stages of ear diseases can now be kept.

The camera takes pictures 120 times as large as the inner ear. With the use of a special concave mirror, a powerful beam of cold light is focused ingeniously into the patient's ear. The exposure is made through a hole in the center of the reflecting mirror

which is turned to deflect the light from the lens of the camera. Heat is extracted from the light beam by passing it through a flat glass flask filled with ice water before it reaches the ear. A clever ground glass arrangement fitted into the side of the camera enables the surgeon taking photographs of the inside of an ear to see the image which is passing through the camera lens even when he is operating the shutter. Thus he can see exactly the image that falls on the plate or film.

Dr Millar is now at work on a camera which will take the picture of the back of the eye. He predicted that soon a camera will be developed to photograph the inside of the human head from the inside.—*Science Service*

where in connection with another case The histologic finding in the present case substantiates the observations laid down at that time

We tried to get some idea of the source of infection in this case The house in which the patient was living appeared to be very unhygienic, but the walls and the floor of the dirty grocery store and the cellar beneath were unsuccessfully searched for molds or fungi The other members of the family did not show signs of blastomycosis

BONE LESIONS

One of us (L R L) collaborated in preparing this case report with a view to laying down criteria which would permit the recognition of cases of blastomycosis from the roentgen-ray appearance of the bone lesions

Potter (6) describes the lesions as occurring most frequently in the long bones near the epiphyses There is rarefaction and a rather marked periosteal proliferation The bone surrounding the focus shows little change He summarizes by saying "Such a marked localizing destruction occurring within spongy bone of a diaphysis, together with a mature and homogeneous periosteal proliferation with or without cloaca, is so constantly present in the ordinary lesions of blastomycosis that when seen in further skiographs where the etiology has not been determined, a careful search for blastomycetes should be made"

Carter (1), in a very excellent review of coccidioidal granuloma, summarizes by saying "The resemblance to blastomycosis is greater than to tuberculosis and distinction would seem difficult if not impossible" He lists lesions of the bony prominences such as the poles of the patella, acromion or coracoid processes or angles of the scapula olecranon or styloid processes of the ulna styloid processes of the radius, condyles of the humerus, extremities of the clavicles, of the malleoli, tuberosity of the tibia, solitary

marginal lesions of the ribs, localized destructive lesions of the outer table of the skull, and destructive lesions of the various parts of the vertebrae as being distinctive of coccidioidal granuloma.

Considering the data of the literature from the radiologist's point of view, the bone lesions of this case resemble coccidioidal granuloma more than they do blastomycosis Nevertheless, the bacteriologic examination revealed typical blastomycetes, therefore, we are led to the same conclusion as Carter (1), cited previously

It seems possible, however, to differentiate with the X-ray purulent and tuberculous osteomyelitis and metastatic bone tumors from bone lesions caused by *Coccidioides immitis* and blastomycetes, thus establishing a correct early diagnosis of the latter diseases

TREATMENT

Concerning the treatment of generalized blastomycosis, our case will only increase the number of those which ended fatally, as is the usual outcome of the systemic disease The mortality is nearly 100 per cent In our case, oral and intravenous potassium iodide and neo-arsphenamine evidently had no effect It seems to us that the constantly good appetite of the patient and the evacuation of abscesses with the applied local treatment were more important We have to admit, though, that while treatment served to prolong life, it did not prevent extreme emaciation and the development of other foci Death occurred in extreme exhaustion

SUMMARY

- 1 A case of systemic blastomycosis is reported in a white male who had spent his entire life in New York State

- 2 The disease was characterized by

millampere meter we have an instrument reading directly the millampere time product consistently and accurately for times as short as one-half cycle and up to one second. This, when used in conjunction with an ac-

value rapidly decreased as the time lengthened and eventually reached the mean value of 200 ma for sustained exposure. It was noted that the milliamperage decreased as the kilovoltage was decreased below the satura-

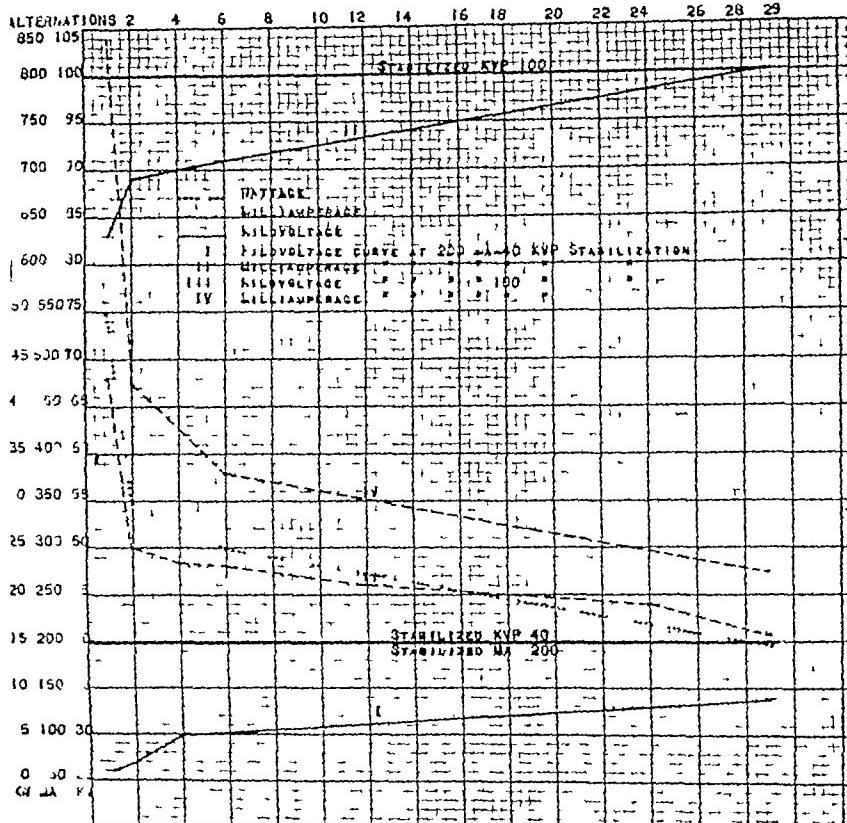

Chart I

curate timer, will allow for the exact computation of current flowing and is the basis for the interesting determinations we have made.

Using the materials described, observations have shown that variations of more than 400 per cent are common in milliamperage and that detection of this variation is impossible except with the ballistic meter. With the Coolidge filament set at the proper point to allow a 200 ma stabilized current to flow through the tube, our data prove that 840 ma were actually flowing when this tube was energized for one alternation. This

tion point of the tube, which in our case was 74 K V P at 200 milliamperes.

Conversely, we find, when energizing the tube under the above conditions, a minimal kilovoltage reading occurs which follows an inverse curve to that observed in the case of the current. A stabilized value of 40 K V P is reduced to 27 K V P for an exposure of one-half cycle. As the time is increased, this value gradually approximates the predetermined sustained kilovoltage.

The difficulties produced by these phenomena are great, as there is neither a stabilized kilovoltage value nor a consistent

FURTHER OBSERVATIONS ON HIGH MILLIAMPERAGE TECHNIC¹

By JOHN D LAWSON, M.D., and EARL H GRAY, M.D.

From the Department of Radiology, Woodland Clinic, WOODLAND, CALIFORNIA

CONSISTENT duplication of radiographic results may be accomplished only when the factors entering into the exposure are subjected to absolute and accurate control and precision. The necessity for this precision is most pronounced when high milliamperage exposures for a short time are utilized. In a previous article on this subject,² one of us (J. D. L.) endeavored to outline the advantages of a technic for chest study embodying high energies for a short-time period.

In an attempt to give this type of radiography the status which we believe it should have, considerable experimental study is being devoted to this subject in the Woodland Clinic Laboratory, the source of these articles. Several important phases will be considered in subsequent communications.

Unless it is possible to give definite factors which will, on all types of equipment, produce the same results, we have not assisted radiology in the solution of a problem, nor have we contributed to the popularization of that technic which seems in our mind to have great advantages.

In this presentation we desire to focus attention particularly on the difficulties, which are brought about by mechanical inaccuracies, surrounding work in the high milliamperage field. We refer especially to the measurement of time, milliamperage, and kilovoltage.

Control of the time factor to a minute fraction of a second may now be accomplished by means of the synchronous timer

which makes and breaks at zero potential, and times varying from 1/120 to $\frac{1}{4}$ second may be accurately and consistently obtained. Previous to the use of this timer, we worked with three ordinary motor-driven timers, none of which could be regulated in any way to approximate consistent duplication. In none of these was an exposure of less than 1/20 second obtainable.

All timers have been checked through the use of the spinning top with a small punch hole in the periphery, giving a recorded proof of the number of electric cycles during which the tube was energized. In this paper we will speak of time in terms of half-cycles, or alternations.

All observations have been made on a four-valve rectified unit with a primary current of 240 volts drawn from a 30 K.W. transformer through 120 feet of 000 copper wire. The same tube, a broad focus universal, has been used throughout. Milliamperages were recorded on two ordinary and one ballistic millampere meters in series.

Kilovoltages were recorded on a 12.5 cm. sphere gap which had previously been calibrated by means of a spectroscope and corrected for temperature, barometric pressure, and humidity. A ballast tube was used in shunt to protect the valves when using the sphere gap.

Until recently, the reading of milliamperage has been confined to the use of a standard millampere meter which necessitates that energy be applied for at least one second before stabilization of current is reached. This length of time must elapse before the forces of inertia and momentum are overcome and an accurate reading may be obtained. However, in the ballistic mil-

¹Read before the Radiological Society of North America at the Sixteenth Annual Meeting at Los Angeles Dec. 1 to 5 1930

²Lawson, John D. High Milliamperage Technic. RADIOL., November 1930, XV 575 578

ly applied, have assisted greatly. We may now measure kilovoltage and milliamperage accurately even for a period of 1/120th of a second, which time may also be accurately obtained. It is a rather expensive procedure to calibrate machines, but, of course, more expensive to develop the various defects which have been carried through the years of ra-

diological development. However, once these points are eliminated, which they will be one by one, we feel that it will become possible for the standard technical set-up to be used universally. A continuation of the work on this subject will probably produce many other observations which have bearing on the subject presented herewith.

CANCER CLINICS DECLARED OF GREAT COMMUNITY VALUE

If a cancer clinic can be made popular in a community it will tend to keep patients from going to cultists and charlatans, is the opinion of Edward J. Klopp, M.D., of Philadelphia, who discussed the advantages and organization of such clinics at the meeting of the American College of Surgeons.

"The patient receives careful consideration, good advice and the best treatment the hospital of the community affords," Dr. Klopp said.

The staff of such a clinic in the general hospital of a large city should include specialists in surgery, in pathology for examination of tissues to determine whether or not they are cancerous, in X-ray work, in radium and electrical treatments, in internal medicine, syne-

cology, skin diseases, urology, ear, nose, and throat diseases, a bronchoscopist, a chemist, a social service worker, and stenographic and technical assistants, according to Dr. Klopp's outline.

If there is opposition to the formation of a cancer clinic, it can be established purely for consultation and follow-up work, Channing C. Simmons, M.D., of Boston, pointed out in discussing the tumor clinic of the Massachusetts General Hospital.

"A hospital is established primarily for the treatment of the sick. It is necessary to prove to the trustees and staff by the work of its members that the treatment advocated by the cancer clinic gives a larger percentage of cures in the early cases and a longer span of life in the hopeless cases," Dr. Simmons said.—*Science Service*

current flowing for the first 30 alternations True, the calibration of any machine may be accomplished and results be duplicated, but to expect the results obtained on one unit to be applicable to another will certainly meet with disappointment

Calibration of a mechanically rectified unit, while not complete, seems to indicate that it also shows a marked variation in kilovoltage and milliamperage but the curves will vary considerably from those obtained on the valve equipment

It is the intent of the writers to attempt to clarify, in further articles on the subject, the many questions which are brought to the surface in this paper The exact bearing and relation of surges, transformers, capacity of primary line, individual rectifying variations, type of rectified wave, and many other factors must be considered before final judgment is formed

It is in order, however, in view of the information at hand, to state that, without accurate timing and measurement of milliamperage through use of the ballistic milliamperc meter and careful determination of the kilovoltage factor, no satisfactory work may be accomplished in the high current field All other factors remaining the same, careful and accurate calibration of equipment will permit of reduplication of results and accomplish the desired effects

DISCUSSION

DR. JOHN R. CARTY (New York City) I cannot add much to the discussion of Dr Hunsberger's paper (see p 320) We adhere to a standard technic, deviating only when special occasion arises, which in our experience has been rather infrequent

As regards Dr Lawson's paper, I wish to commend him for his painstaking work in developing high powered radiography As a result of the increasing interest in speed radiography many undoubtedly will install suitable apparatus Unless, however, there is a thor-

ough comprehension and consideration of all the known factors there will be many costly disappointments and fast radiography will suffer condemnation For instance, if the primary source of current is not adequate the results will be extremely poor Installations of high powered radiographic apparatus have been made, only to find that the source of current is unsatisfactory, necessitating expensive alterations I feel that there is a great future in this type of work as motion during exposure is one of the greatest enemies we have to contend with in producing satisfactory radiographs

DR. LAWSON (closing) When we had completed our study, Dr Gray remarked, "You know, it seems a rather unsatisfactory proposition to present work which contains a great deal of destructive criticism without having anything of a constructive nature attached to it" It was Dr Gray's idea that this work was almost entirely destructive, but, after reviewing material which has been presented, I believe the morals which may be drawn from it are such that the facts presented must be considered as constructive in nature inasmuch as we have called to the attention of radiologists that we have in the past been working with unknown factors Our timers have been inaccurate, the exact amount of current which is flowing during a short interval could not be estimated, and kilovoltage determinations have not been made as frequently as possible One laboratory can reduplicate the results of another laboratory, providing the two laboratories speak the same language or have their equipment calibrated accurately so that the units are interchangeable, and when it is possible to have one laboratory indicate a type of exposure to be instituted in a similar institution two thousand miles away, and be assured of a satisfactory result, we feel that considerable has been accomplished A primary hindrance in radiographic work has been inadequacy of equipment, or, one might say, the lack of satisfactory measuring apparatus There have been certain mechanical and electrical developments within the past year, which, when commercial-

suit the requirements of this case, a minor fracture would have been inconclusively shown, and an important fracture would have been completely missed.

In cases in which full extension of the elbow is not possible, the same principle requires that two anteroposterior views of the elbow be made. One view should be taken with the condyles of the humerus as close as possible to the plate, and one view with the head of the radius as close as possible to the plate. According to my experience, fractures of the head of the radius are among those most likely to be missed, hence the greater need of the two anteroposterior views in the circumstances mentioned.

In skull examinations, by adapting the technic, a fracture may be demonstrated the existence of which would otherwise not be suspected. This was first shown to me by a hospital case in which routine stereoscopic views of the skull in four directions were pronounced negative by a competent roentgenologist. The interne on the case was astonished at the negative findings. In viewing the films, he pointed to a very faint line in the region where, clinically, he had every reason to suspect fracture. The line certainly bore no resemblance to the ordinary fracture line, and he who diagnosed it as such would certainly have been rash. At my suggestion, we had the patient return to the X-ray laboratory, where we placed the suspected area directly upon the plate and took an oblique view. The result was a fracture line that stood out so clearly no one could question it. Even the technician could see it plainly on the wet film. The oblique view of the skull showed a long vertical fracture of the posterior part of the parietal bone, which was not shown in the stereoscopic lateral projection.

In addition to closeness of the fracture to the plate, a second factor of great importance is the direction of the ray with relation to the line of fracture. If the central ray is parallel to the line of fracture, or nearly so,

the fracture is likely to be registered on the plate, if not, it may be missed. As fractures may occur in any plane, the greater the number of directions from which the ray strikes the suspected part, the greater the number of fractures that will be shown. In practice, this means that the part should be placed in as many different positions as possible, or practicable, for exposures. In a series of 1,035 fractures encountered in the X-ray Department of the United States Marine Hospital, San Francisco, 36, or 3.5 per cent, were recorded as being shown in only a single view. In all these cases the examination included three or more views. If only anteroposterior and lateral views had been made, these fractures would have been missed.

The routine examination of the wrist, in the majority of laboratories, includes three views, the anteroposterior, the lateral, and the oblique. If any of these is omitted, numerous fractures will be missed. In the ankle, the oblique view is especially well adapted to show fractures through the posterior portion of the articular end of the tibia, the so-called Cotton fractures, which frequently accompany fractures of the malleoli, or of the distal ends of the tibia and fibula. Cotton fractures are usually vertical, involve the joint, and are accompanied by no displacement. Many of them are missed in the lateral view, but, since the accompanying fractures are usually shown, perhaps no great harm is done. In a certain percentage of cases, however, a Cotton fracture, unaccompanied by any other fracture, will occur in such a plane that it can be shown only by the oblique view.

As the bones of the shoulder girdle, with their processes, extend in so many different planes it could hardly be expected that routine stereoscopic views in only one direction would show every fracture. Nevertheless, it required the following case to teach me this fact.

The surgeon in charge of the out-patient

ADAPTATION OF TECHNICS TO INDIVIDUAL CASES

SOME SPECIAL VIEWS THAT HAVE PROVED VALUABLE¹

By HARVEY S HUNSBERGER, M.D., SAN FRANCISCO

THE difficulty of accurate fracture diagnosis was first forcibly impressed on me by a case of fracture of the os calcis. Clinically the ankle was suspected, but the usual ankle films were negative. Next, request was made for films of the os calcis. Satisfactory views, both lateral and vertical, were negative. Films of the metatarsals were then requested, but the metatarsals showed no fracture. However, the oblique view of the metatarsals showed very clearly a transverse fracture $\frac{1}{2}$ inch deep in the anterior articular surface of the os calcis. In this case, only *one film out of seven showed the fracture*, and that film was made for the study of an entirely different part.

In general, more fractures will be demonstrated, and doubtful fractures will be made clear, if the part suspected clinically or after an examination of preliminary films is brought as close as possible to the plate. In many instances, this may necessitate a departure from routine or standard positions. For instance, in making special views of the carpal trapezium (os multangulum majus) dental films were used. The wrist was so rotated that the lateral border of the trapezium, where the fracture was suspected, was brought close to the small film. The dental negative demonstrated the fracture clearly, but the usual views of the wrist, though of good technical quality, did not show the lesion clearly enough to permit a positive diagnosis.

The principle above stated has its application to the foot. In the routine examination of the foot, three views are usually included, the anteroposterior or vertical, the oblique, and the lateral. In all of these

views, however, the posterior ends of the first three metatarsals are considerably removed from the plate, owing to the upward convexity of the longitudinal arch of the foot. This is also true of several of the tarsal bones, notably the scaphoid and the three cuneiform bones. When a lesion of any of these bones, or of their joints, is suspected, it is important to take postero-anterior views. The patient is placed prone, with the foot in extreme dorsiflexion on an angle board, the ankle being higher than the toes. The tube is tilted about 15 degrees from the perpendicular toward the head, being centered over the bases of the metatarsals. The following case illustrates the importance of this view.

W K came to the laboratory Aug 29 1930, for examination of the left foot and ankle. The following report, in part, was rendered: "No important fracture of the bones of the left foot or ankle can be made out. There is a small, irregular fragment of bone lateral to the base of the first metatarsal that may have been separated by a crushing fracture. This is not certain. If the matter is of sufficient clinical importance, further light might be shed by special views, but it is possible that such views might not furnish a definite answer to the question."

On Sept. 15, 1930, the patient returned for additional studies, and the following report was made: "Special views of the left foot designed to bring out detail at the bases of the first to third metatarsals, with similar views of the normal foot for comparison show a fracture of the base of the third metatarsal in the horizontal plane, separating a fragment 1.5 cm long. The fracture involves the joint."

If the technic had not been adapted to

¹Read before the Radiological Society of North America at the Sixteenth Annual Meeting at Los Angeles Dec. 1-5, 1930.

DR. D M CHRIST (Glendale, Calif.) This paper brings up a point which I believe should be mentioned here. We are often unable to collect payment for the number of films necessary to arrive at the proper diagnosis, and the insurance companies frequently object to multiple exposures for the detection of injuries in cases in which fractures are suspected.

I remember being at the San Diego meeting in the Radiologic Section a year ago last summer at which one of the members of the Industrial Commission told the Radiologic Section that we were supposed to have a right to demand a sufficient number of exposures to arrive at an intelligent diagnosis. He further stated that the Industrial Commission would no doubt bear us out in a reasonable number of exposures.

On two or three occasions I have received letters from the attorneys for the industrial insurance companies, stating that they had reduced the bills because of unnecessary exposures, and were inclosing checks for the amounts which in their judgment were correct.

In one such instance, my very resourceful secretary defeated this encroachment by writing the attorney that the charges and the exposures were those which were regularly routine as recommended by the Industrial Commission, and, since our charges were correct, we would hold the check until such time as he saw fit to send the balance due. We later received another letter indicating failure of the attorney to understand. We wrote in detail, explaining the necessity of the total work done, and mentioning the rulings of the Industrial Commission in these cases. We further offered to interview personally the attorney to explain the necessity and nature of the

work. If the attorney was still unconvinced regarding the matter, we advised him that we would arrange for a hearing by the Industrial Commission. The correspondence convinced this attorney without his even coming to see me and without any further trouble whatever.

Now, whether he was convinced by my explanation or whether he thought he would see the light when he got before the Industrial Commission I do not know, but it is necessary for the radiologist to emphasize the importance of his position. Even if one has to go to the expense of bringing some of these attorneys to a hearing before the Industrial Commission, I feel it should be done. All the money that the attorneys for an insurance company can divert from the roentgenologists' fees may accumulate to an amount sufficient to impress the company directors with their attorney's worth, but it appeals to me as being very unfair to us. I merely relate this as a system which I have developed during a good many years in working for industrial insurance companies, and I find that, after they are brought to a full understanding, the difficulty is soon eradicated. If we, as radiologists, will stand upon our rights and follow this matter through to the proper settling of affairs, it will not pay us personally from the standpoint of dollars and cents, but many individual efforts toward bringing the light to these people will benefit the whole radiologic association.

DR. HUNSMERGER (closing) Perhaps I shall take Dr. Stone's suggestion and present this matter to the surgeons at some meeting. Of course, the entire point of the paper is that the diagnosis of fracture is far from a simple matter.

department of a hospital requested X-rays of a patient's shoulder, suspecting fracture of the clavicle. The usual stereoscopic anteroposterior views were negative. The surgeon could not understand this, as he felt both crepitation and movement. Review of the films, which were technically satisfactory, disclosed no fracture to the surgeon or the roentgenologist. The clavicle appeared perfectly normal. The patient, however, was returned to the laboratory, and a postero-anterior projection was made. This view showed an unmistakable fracture of the clavicle, some separation of the fragments.

Fractures of the scapula undoubtedly fail to show in the anteroposterior view more frequently than any other fractures about the shoulder. If the arm is elevated in a special anteroposterior view, fractures of the axillary border of the scapula will be found that would otherwise be missed. Even this view may fail to show a fracture of the axillary border, which may be seen only in the anterior projection. Since I have discovered that a fracture of the spine of the scapula also may fail to manifest itself except in the anterior projection, an anterior projection of the shoulder is part of the routine examination in the laboratories of which I have charge.

Fractures of the acromion process of the scapula near its tip are common. Since the anterior end of this process lies almost in the coronal plane, such fractures are not easily seen. Special anterior projections, made with the shoulder on an angle board tilted toward the head and toward the feet, respectively, and with the tube tilted about 10 degrees toward the head or toward the feet to correspond, may aid in demonstrating these fractures.

From stereoscopic views, one gains a more accurate perception of relations. When the relations are complicated, as in the numerous bones of the wrist and foot, and in the astragalocalcaneal joint with its

irregularities, stereoscopic views, with similar views of the normal part in exactly the same position, for comparison, will often clear up a difficult fracture. Such views are also valuable in detecting minor degrees of dislocation, especially of the carpal bones, which are otherwise virtually beyond detection.

SUMMARY

Routine radiograms sometimes fail to reveal fractures that are present. Special views sometimes do reveal them. In making special views, the part should be brought as close to the film as possible and projections made from as many different angles as possible.

DISCUSSION

DR ROBERT S STONE (San Francisco) I think that a paper such as Dr Hunsberger's should be presented before an audience not exclusively of radiologists. Our excuse for existing as roentgenologists on fracture work lies in the very point Dr Hunsberger has brought out. If we are going to be merely technicians, taking only anteroposterior and lateral views of the cases that are sent in to us and reading only those views, then the average surgeon dealing with fracture work can handle the case just as well, or better, than we can. Our reason for existence in fracture cases is that we understand the principles of projection of these different fracture lines and on a great many of the cases that come to us we must use other than routine views to arrive at a diagnosis. Our medical training and special X-ray training have to be adapted to this work, and it is our sole excuse for being specialists in this field. I should certainly like to see a paper of the type of Dr Hunsberger's put before the surgical section of the American Medical Association or some other general meetings so that others may realize the detection of even fractures is not so simple as a great many general men consider it.

crease in the density of the bone, and the vault of the skull presents a peculiar serrated appearance An X-ray examination should be made of all patients with chronic bone pains

In the advanced stages the appearance and gait of the patient are highly characteristic The short squat figure with bent shoulders, curved back, sunken chest, long arms, and great head hanging forward, waddles along with bowed legs, out-turned toes and the aid of a stick, the living justification for the term "osteitis deformans"

Although this disease is slowly progressive, it may not shorten life, and is compatible with unimpaired mental activity

The etiology of Paget's disease of the bone is unknown Paget, himself, regarded it as a chronic inflammatory condition French workers consider that it is a late manifestation of syphilis, congenital or acquired In this age it is only natural that the opinion should be expressed that the condition is due to disorder of the ductless glands The undoubted relation of the pituitary gland to acromegaly lends considerable support to this view Hawk has demonstrated metabolic changes of importance There is a marked retention of calcium, magnesium, and phosphorus, and a large elimination of sulphur As calcification proceeds, the sulphur is replaced by calcium, magnesium, and phosphorus, being then excreted in the urine

Since it is a disease of advancing life, there is no question of disturbance of ossification along the epiphyseal line Instead, the condition is one concerned with extensive resorption of the normal bone by osteoclasts and the excessive new formation by the osteoblasts of irregular bony lamellæ which accompany the fibrous marrow The marrow actually loses its blood-forming elements, becoming converted into a vascular fibrous tissue which produces much soft, bone-like tissue

The architecture of the bone is disorganized, and the cortex loses its dense character and sharp outline The marrow cavity is encroached upon until it is filled completely, a thick subperiosteal layer being formed In this new tissue the lamellæ run in every direction and occasionally there are cysts or spaces filled with fluid, or tumor-like growths may appear

In the early stages of the disease the bones are so soft that they can be cut with a knife, but later they may become extremely hard As already indicated, the essence of the disease is bone absorption, associated with, or followed by, increased bone formation The bone absorption leads to great enlargement of the haversian canals

In Paget's original specimens there were innumerable apertures for vessels, and the whole skull was finely porous Cole, in a recent paper on the pathology of Paget's disease, lays great stress on the vascular changes in a case which he examined The vessels in the bones showed varicosity, thrombosis, congestion, hemorrhage, and leakage with edema Cole says, "My impression is that we have a primary blood vessel pathology such as one sees in syphilis, hereditary or acquired, with accompanying bone changes" The vascular lesions he considers infectious in origin

Absorption is followed by the formation of new osteoid tissue, soft and pliable at first, but later becoming rigid through the deposition of lime salts The new bone is chiefly deposited from the periosteum, but a slight deposit may take place from the medulla. The medullary cavity becomes obliterated, although not by the formation of any dense bone, and is filled with a vascular fibrous tissue which may produce soft osteoid tissue The diploë of the skull disappears and the distinction between the outer and inner tables is lost

Paget's disease is a strong predisposing cause towards the development of sarcoma

CLINICAL AND THERAPEUTIC CONSIDERATION OF OSTEITIS DEFORMANS¹

By WEBSTER W BELDEN, M.D.,² and ALICE R. BERNHEIM, M.D.,
New York Hospital, NEW YORK CITY

THIS rare and interesting condition, the exact nature of which is still unknown, was first described by Sir James Paget in 1876. It begins usually after the age of 40. The youngest case that the authors have been able to find reported is that of a patient in Dr LeWald's series who was 31 years of age when the disease was first noted.

The essential feature of the disease is an associated softening and overgrowth of bone, with persistent bone pains forming the chief subjective symptom in the earlier stages. As to clinical features, the bones principally affected are the skull, the vertebrae, and the bones of the leg, but almost any bone may be involved. As a rule the disease manifests itself in a number of bones, but in rare cases it may be confined to one, the diagnosis being then a matter of great difficulty. The bones of the lower limbs are usually the first to be affected, but in a number of cases the disease has been known to commence in the skull. The softened bones of the leg, having to bear the weight of the body, become bent, the femur bends outward, the tibia forward. The patient, therefore, becomes bow-legged. In addition to the bowing there may be a marked twisting, so that, as DaCosta remarks, "The femur comes to look as though it had been grasped by the hands of a giant, bent into a bow, then twisted."

Other factors, in addition to that of body weight, must be responsible for the deformity, for the bones of the arm also become bent, although to a lesser degree. In this

case the curve is backward. Associated with the bending, or even before it occurs, there is a characteristic thickening of the bone. The bone pains, which are so constant a feature of the disease, are felt particularly in the legs, seldom in the arms or head. They may be continuous or periodic and may appear many months before any gross lesion can be detected.

Enlargement of the skull is almost always present at some stage of the disease. It may be the first sign to appear, and may attract attention through the patient noticing that he has to buy hats of ever-increasing size. The deformity in typical cases is so characteristic that it can be recognized at a glance. The head becomes a triangle, with the base above, the face usually escaping almost completely. The enlargement is due to an enormous deposit of bone on the outside of the cranium, there is no endocranial thickening. To those cases in which the facial bones and the bones of the skull are thickened whilst the other bones escape, the name "leontiasis ossea" is given.

The vertebral column is almost always involved, and marked kyphosis develops in the dorsal and lower cervical regions. As a result of the kyphosis, the patient shrinks in height, a condition which is aggravated by the bowing of the legs. There are cases in which a man has lost as much as a foot in stature.

The clavicles may be affected, and, in exceptional cases, the bones of the hands and feet. The pelvis may be broadened, the ribs thickened, and the chest deformed.

The X-ray examinations show characteristic changes long before any deformity appears. There is great thickening and in-

¹Read before the Radiological Society of North America at the Sixteenth Annual Meeting at Los Angeles, California Dec. 1-5, 1930.

²Doctor Belden died shortly after presenting this paper before the Radiological Society. John Remer, M.D., his friend and associate, read the manuscript with the purpose of carrying out any changes which Dr. Belden might have made.

crease in the density of the bone, and the vault of the skull presents a peculiar serrated appearance An X-ray examination should be made of all patients with chronic bone pains

In the advanced stages the appearance and gait of the patient are highly characteristic The short squat figure with bent shoulders, curved back, sunken chest, long arms, and great head hanging forward, waddles along with bowed legs, out-turned toes and the aid of a stick, the living justification for the term "osteitis deformans"

Although this disease is slowly progressive, it may not shorten life, and is compatible with unimpaired mental activity

The etiology of Paget's disease of the bone is unknown Paget, himself, regarded it as a chronic inflammatory condition French workers consider that it is a late manifestation of syphilis, congenital or acquired In this age it is only natural that the opinion should be expressed that the condition is due to disorder of the ductless glands The undoubted relation of the pituitary gland to acromegaly lends considerable support to this view Hawk has demonstrated metabolic changes of importance There is a marked retention of calcium, magnesium, and phosphorus, and a large elimination of sulphur As calcification proceeds, the sulphur is replaced by calcium, magnesium, and phosphorus, being then excreted in the urine

Since it is a disease of advancing life, there is no question of disturbance of ossification along the epiphyseal line Instead, the condition is one concerned with extensive resorption of the normal bone by osteoclasts and the excessive new formation by the osteoblasts of irregular bony lamellæ which accompany the fibrous marrow The marrow actually loses its blood-forming elements, becoming converted into a vascular fibrous tissue which produces much soft, bone-like tissue

The architecture of the bone is disorganized, and the cortex loses its dense character and sharp outline The marrow cavity is encroached upon until it is filled completely, a thick subperiosteal layer being formed In this new tissue the lamellæ run in every direction and occasionally there are cysts or spaces filled with fluid, or tumor-like growths may appear

In the early stages of the disease the bones are so soft that they can be cut with a knife, but later they may become extremely hard As already indicated, the essence of the disease is bone absorption, associated with, or followed by, increased bone formation The bone absorption leads to great enlargement of the haversian canals

Paget's disease is a strong predisposing cause towards the development of sarcoma

of bone, which has occurred in nearly 10 per cent of the recorded cases

We are becoming more convinced that this group of bone diseases has some relation to metabolic unbalance governed by the ductless glands, the gland which is probably responsible being the parathyroid. This seems rather definitely established in osteomalacia but is still a moot point in regard to osteitis deformans and generalized osteitis fibrosa cystica.

It seems appropriate to state here that the localized form of osteitis fibrosa cystica does not belong in the same class as the generalized type described by von Recklinghausen. The consensus of opinion to-day seems to indicate that the localized form is a chronic non-suppurative osteomyelitis, with which theory we are heartily in accord, with the exception that we do not feel that it is to be classed with the non-suppurative sclerosing type of osteomyelitis as described by Garré. To substantiate this claim we rely on the appearance of the lesions in the radiographs. In the former, the X-ray appearance is very much like the generalized form of osteitis fibrosa cystica and osteitis deformans, but it does not show the dense ivory-like appearance so characteristic of the sclerosing osteomyelitis of Garré.

A differential diagnosis among localized osteitis fibrosa cystica, the generalized form, and Paget's disease is often of the utmost difficulty. We are still of the opinion that generalized osteitis fibrosa cystica and osteitis deformans are different manifestations of the same disease at different age-periods of life, but, as stated above, we feel that the localized form of osteitis deformans is due to a previous infection which causes a sterile non-suppurative osteomyelitis or osteitis

When one enters upon the discussion of the therapy of osteitis deformans, or Paget's disease, and reviews the literature on this subject, it is found that practically all the drugs included in both the American and

British pharmacopeia have been used from time to time. For the past few years at the New York Hospital we have been treating these cases by the administration of calcium lactate, Vitamin D (viosterol), and tomato juice.

The following is the description of the theory and detail of the therapy used.

One of us (A. R. B.) has been particularly interested in the question of calcium metabolism and feels that the study of calcium, especially in its relation to the parathyroid glands, may be helpful in an attempt to gain an insight into the nature of these disorders. Observations have resulted in the development of a concept of the subject which may be stated as follows:

The parathyroid glands are mobilizers of calcium. One function of these glands is to control the stream of calcium from the trabeculae of the bones to the blood. The blood depends upon this supply for its normal concentration of calcium, and not upon the supply absorbed through the intestines, which is a very variable factor. Bauer and Aub have shown that on a low calcium intake of 300 mg over a three-day period, 790 mg are excreted, giving a negative balance of +90 mg of calcium. This may be considered the measure of endogenous calcium metabolism. It is interesting to note that no other inorganic substance behaves in this way.

Over-activity of the parathyroids, as in osteomalacia, increases the flow of calcium from the bones with a resulting osteoporosis, increased blood calcium, and increased excretion of calcium. When the glands are under-active, as in tetany, the output from the bones is lessened, and there is hypocalcemia and diminished excretion of calcium.

Another factor of importance in the calcium chemistry of the body is Vitamin D, of which there are two sources. The action of actinic rays on the sterol in the skin produces Vitamin D in the body, and it may be obtained by the ingestion of irradiated er-

state of our knowledge, from what observations we are able to make, over-activity and dysfunction on the part of the parathyroid glands seem to be of etiologic significance in osteitis deformans.

In view of the similarity of all these cases of osteitis deformans we think it would be a waste of time and money to put illustrations of all the cases in this article and are, therefore, showing photographs of the entire skeleton of one of the patients who exhibited characteristic changes.

CASE REPORTS

Case 1 G W N, aged 47 years, was admitted to the hospital on Feb 7, 1927, the chief complaint being deformity of the bones and soft parts, with pain. The illness began three years before the present examination, when the patient noted a small lump on the anterior aspect of his left tibia. This was hard and bony in character and gradually increased in size, but was not painful except when struck. At a slightly later period the left knee began to swell and was painful, becoming stiff. Two years before admission to the hospital the patient, while throwing a baseball, sustained a fracture of the right humerus. Shortly after this had healed he fractured his left clavicle in alighting from a trolley car. About one and one-half years before examination the upper end of the left humerus began to swell and the shoulder to stiffen. The patient was able to abduct the arm only to a right-angle. In December, 1926, the shoulder became very painful and the patient complained of great heat in it, while the swelling increased rapidly.

During the entire course of his illness the patient had noted an increasing bowing of the legs and an increase in the size of his head, stating that it felt lumpy. There was gradual increase of pain in the back and legs. About three weeks previous to admission, a tumor mass appeared on the anterior

aspect of the right humerus, at the site of the previous fracture. At almost the same time the patient noted a cystic swelling in the right temporal region and about a week later two similar, though smaller, swellings appeared on the left forehead. He also complained of difficulty in walking and inability to adduct the left femur, due to a hard bony mass in the region of the lesser trochanter.

The past history comprised the usual childhood diseases but no other diseases or infections. The man had always been athletic in his habits. His family history was negative, except that the cause of his mother's death, at 86 years of age, was unknown. There was no history in the family of disease similar to that presented by the patient.

Physical Examination.—The patient was an under-nourished white male, who appeared chronically ill. Inspection showed a typical enlargement of the cranium and a face triangular in appearance. The anterior bending of the spine and the anterior bending and bowing of the femurs and left tibia gave the typical posture of Paget's disease. Over the right temporal bone was a cystic mass about 4 cm in diameter. In the left frontal region were two firm masses about 1.5 cm in diameter. The left clavicle was prominent and thickened, with a firm mass about the size of a walnut present near the outer end. The heart and lungs were negative. The liver showed some enlargement. The extremities showed bowing of the tibias, especially the left, bowing and thickening of both femurs, and a hard bony mass in the region of the lesser trochanter. The knee jerks were active. The left shoulder showed definite fusiform hard swelling of the upper third of the arm, which impaired the shoulder movement. The skin appeared fairly normal and its temperature was not elevated. Over the anterior aspect of the right humerus, about its middle third,

gosterol Vitamin D has two functions: it increases the absorption of calcium through the intestines, and it activates the parathyroid glands.

In the early stages of osteitis deformans we find osteoporosis, high blood calcium, and increased excretion of calcium. From these findings we may postulate an over-activity of the parathyroid glands. Later in the disease, when the formation of osteoid tissue and the erratic deposition of calcium in the bones occur, the blood calcium is found to be low and excretion is diminished. At first glance it would seem that under-activity had followed upon the preceding over-activity, but, by the token that calcium is deposited abnormally in large amounts in the bones, over-activity may be said to persist with *deranged* activity as an added factor.

In a study of eight cases, a low normal blood calcium (9 to 9.5 mg./100 cc.) was found in four of the cases in which the duration of the disease was known to be five years or more, whereas, in the other four cases, which were of shorter duration, the blood calcium was found to be above normal (11 to 12.3 mg./100 cc. of blood).

Since bone destruction was going on in all of these cases irrespective of their duration or other processes, we wanted to see in what way, if any, a high calcium intake would affect the calcium situation. Calcium lactate, or milk, and Vitamin D were given, also Vitamins A, B, and C. On this regime headache, backache, and stiffness in the legs were alleviated. There was marked improvement in the ability to walk and in three cases the patients abandoned their canes, without which they had been unable to get about. One woman had not been able to get up from a chair or to walk without assistance. She had had pains in her thighs and back. Improvement in her condition, which was marked after three weeks' treatment, has been continued for over two and one-half years. She is able to do her housework,

walks without a cane, and has been free of pain up to the present day. In this case, roentgenologically, there is no evidence of advance in the disease. In one other case, in spite of improvement in symptoms, there is marked progress in the bony changes, especially in the skull, which has increased in size during two years of observation and treatment.

Before coming to the New York Hospital, a number of patients had received calcium treatment without improvement. Administration is unavailing unless due regard is given to the conditions under which calcium is absorbed, which does not take place unless the digestive tract is empty.

Our regime is as follows:

Viosterol, drops X, three times a day,
Tomato juice, 6 ounces, three times a day,
Calcium lactate, gr XL, twice a day.

This is given one hour before breakfast and four hours after supper, or, if the second dose keeps the patient up too late at night, it may be given four hours after luncheon and one hour before supper. This regime is followed for two weeks, then three glasses of milk a day are substituted for the calcium lactate. A long continuance of the administration of calcium lactate often results in frequency of urination, hence alternating milk with the calcium lactate is found advisable. Every fourth week viosterol is discontinued for five days.

Treatment with parathyroid extract was next tried. The blood calcium was raised, as it was with the high calcium and vitamin regime, but there was no improvement in symptoms, in fact, the patients felt generally worse than with no treatment at all. Parathyroid extract increases the blood calcium by taking it from the trabeculae, which apparently, in this disease, are already giving it up excessively.

We are handicapped by the lack of instruments of precision for measuring the calcium situation *in vivo*, but in the present

The present condition showed nothing unusual except for the subjective symptoms. The family and past histories were irrelevant. The physical examination was entirely negative except for slightly hyperactive knee jerks and slight hyperactivity of some of the other tendon reflexes. The positive findings were that the history suggests a *petit mal* (Jacksonian epilepsy), slight sluggishness of the right pupil, slight deviation of the tongue to the right, large square head, slight impairment of hearing on the right side, and marked loss of weight.

X-ray Examination—The gastro-intestinal tract showed spasm of the pylorus, but was otherwise negative. Examination of the gall bladder was negative. The liver shadow seemed to be slightly enlarged. There was definite condensation of the body of the fourth lumbar vertebra, indicating an increased density of the bone due to calcium deposit, which suggested the sclerosing type of carcinoma metastasis. The bones of the skull showed marked thickening and mottling, with distinct rounded areas of increased density in both parietal areas, as well as rarefied areas. There was a slightly similar process in the right ischium and greater trochanter of the right femur. These findings were interpreted as osteitis deformans (Paget's disease).

The urinary examination was negative.

Blood Examination—Red cells 4,256,000, hemoglobin, 100 per cent, white cells, 6,400, polymorphonuclears, 74 per cent, lymphocytes, 24 per cent, Wassermann, negative.

During the patient's stay in the hospital he was afebrile, the pulse and respiration were normal.

Summary—This patient was evidently suffering from either epileptiform attacks or pachymeningitis, as there is nothing in his history that would suggest Paget's disease, although the X-ray findings are unquestionably those of Paget's. This probably means

Fig 1 The characteristic appearance of Paget's disease in the advanced stages—bent shoulders, curved back, sunken chest, long arms, bowed legs.

that the patient has a complication of these two diseases.

Case 3 M. W., aged 42 years, married, was admitted to the hospital on July 24, 1924, with the chief complaints of weakness and insomnia. The past history was negative except for attacks of quinsy.

Present Illness—For some three months the patient had been feeling weak and tired all the time although she had gained about five pounds. Insomnia, with headache in the posterior portion of the head, and pains in both legs had been constant features. In

was a hard swelling nearly the size of a plum. It was fixed, and seemed attached to the bone. In the lower portion of the left arm was a similar hard swelling, but smaller. The left knee showed a generalized swelling, most marked on the inner side. The ankles and feet seemed normal.

X-ray Examination.—Marked cortical thickening, irregularly striated, periosteal bone production and cystic formations were clearly seen in the left tibia, both femurs, the bones of the pelvis, and the spine. In addition, there was a marked increase in the size of the lesser trochanter of the left femur, giving the appearance of a large osteoid tumor. Examination of the skull showed marked deformity and thickening of the cranial bone, with irregular calcific deposits between the outer and inner tables. The right humerus showed the same changes as noted in the other long bones, and a tumor in the soft parts could be clearly seen. The left clavicle also showed degenerative changes and evidence of the old fracture. The upper end of the left humerus was almost completely destroyed, but showed some irregular calcific material in the region of the extensive tumor which invaded the soft parts.

X-ray diagnosis was typical Paget's disease, with degeneration and formation of an osteogenic sarcoma.

Laboratory Findings.—The blood showed red cells, 4,592,000, hemoglobin, 47 per cent, white cells, 9,800, polymorphonuclears, 76 per cent, lymphocytes, 21 per cent, Wassermann, negative.

Blood calcium at first, 10 mg per 100 cc., later, 12 mg per 100 cubic centimeters.

Urine analysis negative, no Bence-Jones bodies, urine calcium, 0.211 grams in 24-hour output.

During the patient's stay in the hospital his temperature varied between normal and 99° for the first seventeen days. On the eighteenth and nineteenth days it was 102°.

It then returned to the previous range of from normal to 99° until a few days before death, when it ranged from 100° to 103.5°. A consultation was held and it was decided that the numerous tumor masses were due to sarcomatous degeneration, for which high voltage therapy was advised. The patient was given eight therapeutic exposures to the left shoulder, anterior and posterior, to the lower dorsal and lumbar spine, to the left groin and femur, and the right humerus both anterior and posterior. John Reimer, M.D., gave these treatments, using the following factors 200,000 volts, 4 ma, 50 cm distance, with 0.5 mm copper and 1 mm aluminum filter. The total dose administered was 70 per cent depth dose to the different areas. Though the X-ray therapy resulted in no decrease in the size of the sarcomatous masses or X-ray evidence of changes, there was very marked relief from the patient's symptoms of pain and discomfort. He died on the forty-fifth day in the hospital. No autopsy was obtained.

Case 2.—Mr. McD., aged 59 years, was admitted to the hospital on March 31, 1926, complaining of headache, dizzy spells, and convulsive seizures. He gave a history of two injuries in childhood, with no sequelæ. For the fifteen years previous to examination he had had attacks similar to the ones for which he was admitted, but lately these had grown worse. Two injuries had occurred since the onset of his present illness. These attacks were always preceded by an aura, accompanied by spastic movements of the extremities and loss of consciousness. At times the attacks were limited to a short convolution, at others, they proceeded to loss of consciousness. They varied a good deal, but always started on the right side. Sometimes the man ground his teeth and bit his tongue. The patient had had a large amount of medication, with no relief, and had lost considerable weight. In 1925 he had had an attack of marked epigastric pain.

The present condition showed nothing unusual except for the subjective symptoms. The family and past histories were irrelevant. The physical examination was entirely negative except for slightly hyperactive knee jerks and slight hyperactivity of some of the other tendon reflexes. The positive findings were that the history suggests a *petit mal* (Jacksonian epilepsy), slight sluggishness of the right pupil, slight deviation of the tongue to the right, large square head, slight impairment of hearing on the right side, and marked loss of weight.

X-ray Examination—The gastro-intestinal tract showed spasm of the pylorus, but was otherwise negative. Examination of the gall bladder was negative. The liver shadow seemed to be slightly enlarged. There was definite condensation of the body of the fourth lumbar vertebra, indicating an increased density of the bone due to calcium deposit, which suggested the sclerosing type of carcinoma metastasis. The bones of the skull showed marked thickening and mottling, with distinct rounded areas of increased density in both parietal areas, as well as rarefied areas. There was a slightly similar process in the right ischium and greater trochanter of the right femur. These findings were interpreted as osteitis deformans (Paget's disease).

The urinary examination was negative.

Blood Examination—Red cells 4,256,000, hemoglobin, 100 per cent, white cells, 6,400, polymorphonuclears, 74 per cent, lymphocytes, 24 per cent, Wassermann, negative.

During the patient's stay in the hospital he was afebrile, the pulse and respiration were normal.

Summary—This patient was evidently suffering from either epileptiform attacks or pachymeningitis, as there is nothing in his history that would suggest Paget's disease, although the X-ray findings are unquestionably those of Paget's. This probably means

Fig 1 The characteristic appearance of Paget's disease in the advanced stages—bent shoulders, curved back, sunken chest, long arms, bowed legs.

that the patient has a complication of these two diseases.

Case 3 M W, aged 42 years, married, was admitted to the hospital on July 24, 1924, with the chief complaints of weakness and insomnia. The past history was negative except for attacks of quinsy.

Present Illness—For some three months the patient had been feeling weak and tired all the time although she had gained about five pounds. Insomnia, with headache in the posterior portion of the head, and pains in both legs had been constant features. In

Fig 2 There is typical enlargement of the cranium, the head is a triangle with the base above.

Fig 3 The softened bones of the leg become bent, the femur bends outward, the tibia forward

addition, there had been pains in the eyes, and difficulty in going upstairs, with dyspnea and marked palpitation on exertion. The family and personal histories were negative.

Physical Examination—The patient was an obese woman who appeared chronically ill. She exhibited edema under both lids, ptosis of the right lid, and irregular pupils. The mouth showed fair teeth and diseased tonsils. The lungs were negative, the heart rapid and of poor muscular tone. The blood pressure ranged between a systolic of 110 and 130. The abdomen was negative. The extremities showed slight edema of the ankles. There seemed to be swelling over the left greater trochanter, very slight limitation of flexion, marked limitation of internal rotation, and marked tenderness on pressure over trochanters. The patient's posture in the erect position was bad.

Laboratory Tests—Urine, negative

Blood count, essentially normal. Wassermann, negative.

Basal metabolism was —13. Blood calcium, normal.

The patient was under constant observation until Oct 20, 1927. On October 15 she reported very marked pain in the toes. On examination, they were seen to be shiny and of a bluish-red color, which strongly suggested, both from her description and the physical findings, a beginning thromboangiitis obliterans.

X-ray Examination—The radiograms showed a thickening of the cortex of the upper third of the left femur and some anterior bowing. There was a coarse striation in the region of the greater trochanter and neck, with an occasional small area of decreased density. The pubic bones, right ischium, and the wing of the right ilium showed the same changes. The lumbar spine was negative except for a hypertrophic

osteo-arthritis. The skull showed irregular areas of increased density between the inner and outer tables, which were more marked in the posterior half. There was considerable thickening, particularly in the occipital region. The other bones were negative. The diagnosis was osteitis deformans (Paget's disease).

Summary.—The attending physician's note was as follows: "The X-ray examination showed unmistakably the condition in the left femur, bones of the pelvis, and skull so characteristic of Paget's disease. The patient showed none of the clinical signs of Paget's disease and the age is rather young. It is interesting to note that this patient bears a close resemblance to the myxedema syndrome, in view of the theory that osteitis deformans may result from a calcium imbalance caused by disease of the parathyroid glands."

Case 4 C M., female, 53 years of age, was admitted to the hospital in December, 1923, complaining of swelling of the head, and deafness. For eight or nine years she had noted that her head was increasing in size on the right side. For three or four years she had had pain in her right ear, with increasing deafness. For the last few months before admission to the hospital she had noticed a headache in the frontal region when she coughed. She had been gradually losing weight for the five or six years preceding the examination.

The family history was entirely negative and no similar disease had ever been noted in the family. The past history was as above except that, in addition, the woman had been tiring easily for the previous few years and had had slight dyspnea and palpitation.

Physical Examination.—The patient presented a striking osteitis deformans appearance. She had a vacant dull appearance, was short of stature, and appeared stooped. The head was triangular in shape, with the apex downward. There was an unusually round-

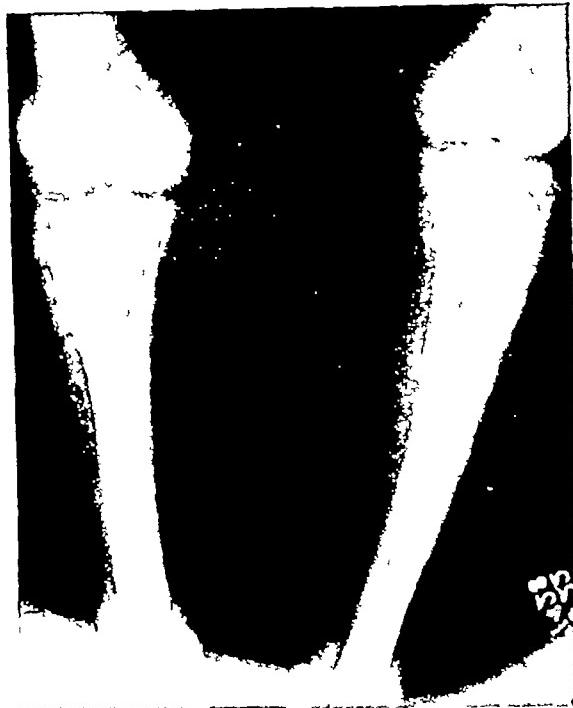

Fig. 4. The architecture of the bone is disorganized by osteitis deformans.

ed prominence on the right side in the temporal parietal region. Palpation of the head revealed thickening at the base of the skull, and increase in bone in both temperoparietal regions, with a definite rounded prominence on the right side. The circumference of the head was 66 centimeters.

The spine showed no definite kyphosis but a definite rounding of the shoulders. The left clavicle was unusually thickened and irregular. The ribs showed no abnormalities. The pelvis was settled and unusually funnel-shaped. There was slight thickening about both elbows in the upper extremities. The femurs did not appear bowed. There was general thickening about both knees and the anterior surface of the left tibia. The tibia was thickened in its upper third. The rest of the physical examination was negative.

The reflexes were all present. The blood count was normal and other laboratory tests showed no changes.

X-ray Examination.—Definite involvement of the skull, both femurs, and the

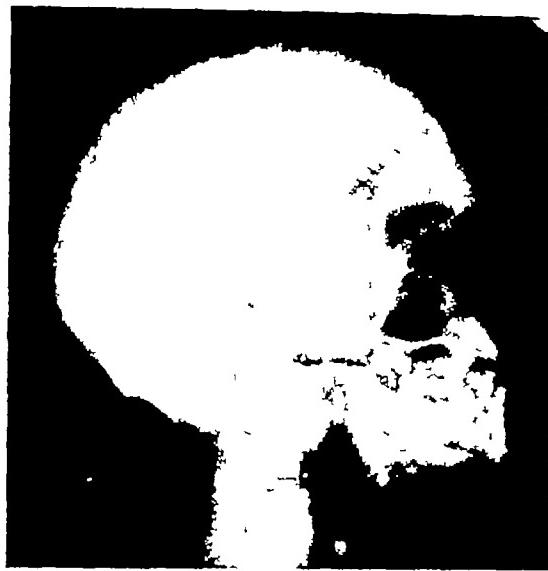

Fig 5. The vault of the skull presents a serrated appearance, and the diploë disappears, the distinction between the outer and inner tables being lost

bones of the pelvis was demonstrated by X-ray examination. There also seemed to be some changes in the ribs and the left clavicle, which showed typical bizarre arrangement in the bone trabeculae, thinning out of the bone, and bizarre calcific deposits so typical of osteitis deformans.

The patient, who was afebrile, left the hospital after staying seven days and no trace of her has since been possible.

Case 5 G C, male, 43 years of age, was admitted to the hospital in August, 1916, for a broken leg. About ten years previous to the present examination, the patient had begun to have pain in the left leg, extending the entire length of the shaft. The pain had been more or less constant up to the time of examination and it was getting gradually worse. Six years before admission to the hospital the patient fell and fractured the left femur just above the knee. The fracture healed, and there had been perfect function of the leg for two years. Then pains began in the right leg and the patient was forced to stop work on account of pain and weakness, and stiffness in both legs and knee

joints. He had been confined to bed almost constantly for two years before examination. In August, 1916, while turning in bed, the patient fractured the left femur about five or six inches above the site of the old fracture.

The history was difficult to obtain as the patient could not speak English. The past history was negative except as described above. The family history was negative.

The fracture was treated and reduced, a circular plaster spica being applied.

X-ray Examination—The patient exhibited a fractured left femur which extended through the shaft. The changes in the bone were quite typical of osteitis deformans.

Laboratory tests were negative.

The patient was discharged early in September, the leg healing. In April, 1917, report was that the patient had been in a city hospital for seven months with disease of the bone which was becoming progressively worse. There was no further follow-up.

The interesting thing in this case seems to be, if the patient's history can be depended upon, that his osteitis deformans started ten years previous to examination, which would make him 33 years of age. This is rather young for osteitis deformans but we feel the changes are so characteristic and the history so suggestive that he must come under this class.

Case 6 Mrs G H, aged 47 years, was admitted on June 30, 1925, to the Bloomingdale Hospital. The patient's family and personal histories were negative except for the mental condition for which she was admitted to the hospital.

The present illness dates from 1921, when a spur was noted on the patient's spine. She was examined by an orthopedic surgeon, who stated that the condition was either tuberculous or due to carcinoma. She was fitted with a spinal jacket, which she wore for a year, at which time she was pronounced well. Six months later it was

Fig. 6 (*upper left*) Enlargement of the skull is one of the first signs to appear in osteitis deformans
Fig. 7 (*upper right*) Fig. 8 (*lower left*) Fig. 9 (*lower right*) The cortex loses its dense character and sharp outline, the marrow cavity is encroached upon

noted that she was becoming round-shouldered, and she complained of pain but there was no local irritation. The patient had

several Wassermann tests made, but all were negative. She attempted to commit suicide by cutting her wrists and exhibited symp-

toms of manic depressive. She lost about eight pounds in weight.

Physical Examination.—The patient was a poorly nourished woman, weight, about 100 pounds, face, somewhat puffy, color, poor, heart and lungs, negative except for a slight cardiac enlargement to the left, with soft systolic murmur, blood pressure, 106/50. There was slight edema of the ankles and the back showed angular deformity in the mid and lower thoracic vertebrae. The face was rather expressionless. The reflexes were slightly exaggerated. The rest of the examination was negative except for slight deformity and slight bending and thickening of the bones of the arms and thighs.

Blood Count.—Red blood cells, 4,500,000, hemoglobin, 60 per cent, white cells, 9,950, polymorphonuclears, 70 per cent. The blood chemistry showed nothing unusual and practically the normal amount of blood calcium.

X-ray Examination.—The spine showed marked changes in the region of the first, second, and third lumbar vertebrae, and obliteration of the normal outlines of the bodies, with displacement of the arterial surface, resulting in kyphotic deformity. These vertebrae showed very marked osteoporosis, giving a distinctly moth-eaten appearance. This condition extended to the sacrum, to both ilia, and the pubic bones. The upper ends of the femurs were likewise involved. The shafts of the femur and tibia were apparently normal. The right humerus showed some osteoporosis, which resulted in a moth-eaten appearance, extending along the middle of the shaft. The left humerus, on the contrary, showed marked defect, including throwing up into ridges of the shaft of the bone, with smaller areas of rarefaction in the lower ends of both radius and ulna. The shaft of the radius was fairly normal in appearance, but the shaft of the ulna had the same moth-eaten appearance.

as noted in other bones. The left radius and ulna were only slightly involved. The ribs also showed a considerable degree of rarefaction, giving them an irregular moth-eaten appearance.

X-ray examination of the chest showed the heart to be triangular in appearance, and enlarged (especially to the left) with a widening of the arch of the aorta. The apices were poorly illuminated. There was no irregularity of either diaphragm. There was considerable mottling at the roots of both lungs, with much increase in the peribronchial tissue. X-ray examination of the skull showed a slight degree of irregular rarefaction, giving a moth-eaten appearance such as is seen in osteitis. These findings were diagnosed as due to osteitis deformans.

The patient was discharged on Nov 16, 1926, much improved, and no further history was obtained.

Summary.—The age at which the onset of the disease occurred, namely 44 years, together with the characteristic X-ray findings, seems to place this case in the classification of osteitis deformans (Paget's disease). The mental symptoms probably have no bearing on the bone disease, though this patient, like the last two cases, showed some abnormal brain condition. Three cases, however, do not seem to be sufficient to warrant drawing any definite conclusions.

Case 7 Mr T., aged 70 years, is included in the series simply for the reason that his right femur and right ilium, ischium, and pubis exhibit the changes which are capable of interpretation as either osteitis deformans or osteitis fibrosa.

The history has no bearing whatever on the case. The patient had always been healthy and the only point which might be regarded as of any significance is that for a number of years he had had what he described as "twinges of rheumatism," and his knee joints, the articulations of the lumbar

vertebræ, and the left hip showed evidences of an hypertrophic osteo-arthritis.

On Dec. 5, 1926, at the age of 69 years, the patient was struck by an automobile, sustaining a fracture of the ninth rib on the right side and a fracture of the neck of the right femur. He was given the usual treatment for the fracture of the femur, remaining in bed for some twelve weeks. A radiograph, taken ten months later, still showed the marked osteoporotic, lacy appearance of the bone, with the mottling by areas of decreased density, suggesting beginning cystic formation. The skull showed no variations from the normal.

Summary—Are we to class this patient as a case of osteitis deformans, localized to the ilium, femur, right ischium, and pubis, or are the changes due to marked atrophy of disuse, accentuated by the patient's age? The evidence in favor of atrophy of disuse seems rather weak, as the radiograph made ten months after discharge from the hospital, while the patient was walking some three miles a day in the course of his occupation, showed the same changes to be present. Frankly, this is unquestionably a case which, in the light of our present knowledge, we cannot definitely classify. However, the atrophy of disuse, it seems, can be ruled out on the unilateral distribution of the changes, which would place the condition either in the group of osteitis deformans or in that of osteitis fibrosa cystica.

Case 8 Mrs. H., white, 57 years of age, consulted her physician for pain in her left leg, with increased anterior bowing of the lower leg. She had noticed this pain for several years but was not definitely sure for how long, the bowing had been present for three years. She paid very little attention to this until she struck her leg against a chair and heard something snap. She then found it difficult, in fact almost impossible, to walk on this leg. The radiographs made at that time showed definite disturbance in

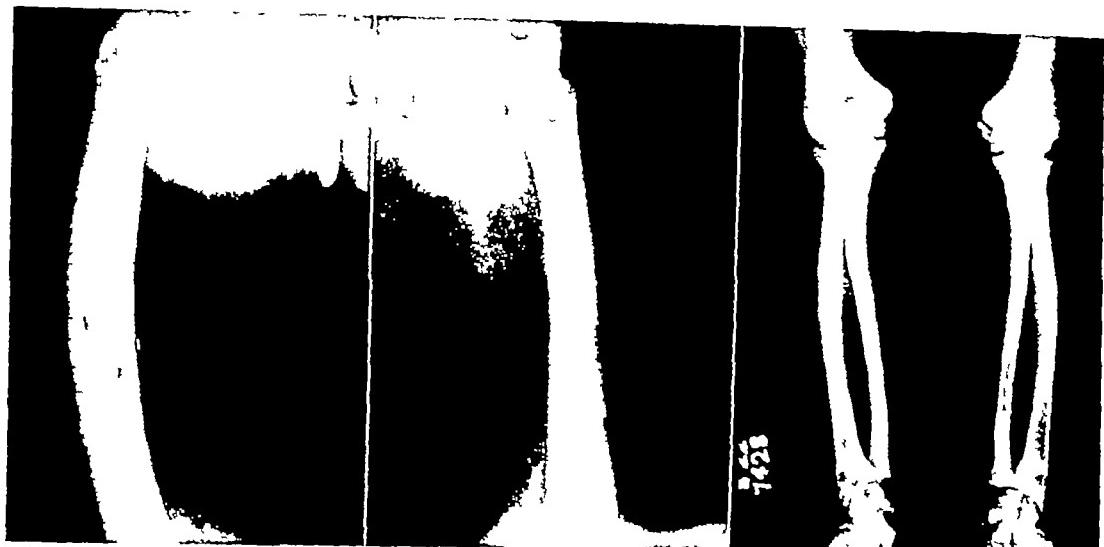

Fig. 10 Broadening of the pelvis is characteristically seen under X-ray examination.

the bone trabeculae, with cystic formation and bizarre calcific deposits with marked anterior bowing of the left tibia. There was also beginning involvement of the lower end of the left femur. The patient denied any knowledge of change in this bone previous to three years before the present examination. She was treated by the application of plaster, whereupon the fracture healed. She was then referred to an orthopedic surgeon, but, upon walking into his office, she turned her ankle and sustained two fractures of the tibia.

In view of the age of this patient and the characteristic changes in the tibia, even though the other bones were negative for any changes, one feels this is probably a case of osteitis deformans.

Case 9 Mrs. E. B., aged 50 years, entered the hospital May 2, 1927, the chief complaints being loss of weight, and weakness.

Present Illness—For eighteen months preceding examination, the patient had noted a feeling of weakness and of being generally below par. Her friends had noticed an occasional swaying as she walked. She, herself, had noticed a tendency to deviate to one side, and a desire to put out her hand to steady herself. Occasionally she felt light-headed, but had only transitory pains.

Figs 11 and 12 A well-defined thickening is associated with the softening of the bones, which, due to the weight, causes the femurs to bend outward

Fig. 13 The bones of the lower limbs are usually first affected, the tibia bending forward.

in the head and no other pains Fifteen months previous to her admission she had had a clinical examination in another institution, but at that time no lesions were found No X-ray examination was made then The patient had noticed an occasional numbness in her hands and weakness in her legs

The past history was negative except for tonsillitis in childhood and swelling of her joints two years before examination

The family history was negative except that the mother died at the age of 76 years from arteriosclerosis

Physical Examination—The patient was a well developed and well nourished adult female, who did not appear acutely or chronically ill She walked with an unsteady gait and showed a tendency to fall toward the right side The rest of the physical examination was negative except for superficial varicose veins in both legs and definite accentuated tendon reflexes in the biceps, triceps, and knee jerks

X-ray Examination—The skull showed typical, irregular, dense, calcific deposits, with the slight thickening of the outer table which is considered characteristic of Paget's

disease The second lumbar vertebra, the ilium, pubes, and ischium on both sides showed some deformity, being of irregular striated appearance and suggestive of cystic formation as the result of osteitis deformans The gastro-intestinal tract was essentially negative

Laboratory Examination—Red blood cells, 4,544,000, hemoglobin, 82 per cent, white blood cells, 7,200, polymorphonuclears, 66 per cent, lymphocytes, 33 per cent The Wassermann test was negative Blood sugar, 0.11 per cent, blood calcium estimation not made Urine no Bence-Jones bodies, negative for sugar and albumin

The patient was in the hospital for some ten days and showed no other points of interest The history and clinical findings were inconclusive, but, from the X-ray examination, the diagnosis was Paget's disease

Case 10 The patient, T S, aged 63 years, was an apartment house janitor who came to the Compensation Department because he had fallen and injured his knee while tending the furnace Physical examination showed thickening of the tibia and slight anterior bowing, but X-ray examina-

tion showed no evidence of fracture. The changes were interpreted from the X-ray findings as due to Paget's disease.

Unfortunately this patient did not return for X-ray examination of the skull and other bones and no past history was obtained, so that one includes this case as illustrative of Paget's disease solely on the X-ray diagnosis.

Case 11 Mr K, first observed in 1914, was at the time of examination 58 years of age.

At the initial X-ray examination a diagnosis was made of small gastric ulcer on the posterior wall, and possibly two small urinary calculi. In 1922, when the patient was again radiographed, the ulcer was not seen, and there was a delay in the third portion of the duodenum. A retrocecal chronic appendix was also diagnosed, and gastric retention was noted, interpreted as due to thickening of the pylorus from the old ulcer. In 1927, the patient was seen by Dr Williams, who elicited the history that in boyhood the patient had had an attack of appendicitis but no operation had been done.

The physical examination was negative. The patient suffered moderately from constipation and had occasional gaseous discomfort, which was relieved by powders. For the three years preceding examination he had had an irritating pain in the tongue, which showed a small induration. He smoked a good deal, was rather nervous, and had bad teeth, but they were being treated. He had no symptoms referable to the head, and had never had any bone or rheumatic pains. His history seemed to be entirely gastro-intestinal.

X-ray Examination.—Radiographic examination, made on Jan 20, 1927, showed a definite sclerosing process in the body of the second lumbar vertebra. A sclerosing process, though not so pronounced, with definite mottling and disturbance in the bone trabeculae, was noted in the left ilium, and,

to a lesser degree, in the right. The patient's skull showed the frontal and both parietal bones to be mottled by definite areas of increased density, which were irregular in outline. These areas were not characteristic of bony metastasis, and, when considered in conjunction with the findings in the second lumbar vertebra, the ilia, and the sacrum, one's impression would seem to be in favor of a diagnosis of early Paget's disease.

Summary.—This is another case in which no history, either family or personal, can be elicited to confirm the X-ray diagnosis of Paget's disease, though the changes noted on X-ray examination are so characteristic that there seems to be no doubt of the correctness of the diagnosis.

Case 12 Mr H is a man past middle life whose X-ray examination showed the typical changes of osteitis deformans. Unfortunately he is a private patient who was referred to the office, so that no history was obtained and none of the laboratory tests was done to our knowledge. We have since lost trace of the patient. We are reporting him in the series simply because of the characteristic bone changes.

Case 13 W R, white male, 37 years of age, was brought to the hospital on April 7, 1930, complaining of pain and stiffness and bowing of the left thigh which had begun 18 months previous to the examination. The family and past histories were negative except for the usual childhood diseases. The patient, who had played professional football for the preceding six years, and who was quite active in other sports, gave a history of many injuries to his head and neck. He had received a fracture of the jaw in 1927. He gave no history of headaches and was subject to very few colds. He had noticed slight deafness in the left ear for a year but no dizziness. Upon close questioning, the patient recalled that his symptoms probably started three years earlier, after an injury to his neck in a wrestling match.

The first symptom was a dull aching pain in the left thigh, with generalized tenderness. About one month later the patient noted a slight bowing of the thigh which progressed slowly for two years. About one year before the present examination, for eight or nine days, there was definite increase in deformity and severe pain, which had now ceased. He had received no treatment.

Physical Examination.—The patient was a man who appeared well—stocky, with a large head. There was slight lateral curvature of the left thigh and a slight waddling gait. The shoulders were slightly stooped and the head was held stiffly. The skull was negative, except for being large. The neck was somewhat stiff on backward motion. The thorax was negative, the lungs clear, and the heart signs normal. The blood pressure was 118/60. The abdomen was negative and there was no tenderness or stiffness in the back. There was some rotation in all joints, most marked in the left hip and right shoulder. The patient exhibited marked crepitus in the large joints and the small joints of the fingers. The left thigh showed considerable forward and lateral bending, which was also present in the right, but less marked.

The patient was given a most exhaustive blood study. The calcium was about normal in all these tests and the other blood findings were also fairly normal. The basal metabolism was +34.

The patient, who remained in the hospital for three months, was afebrile throughout his stay. Studies on his blood chemistry were done during the course of eleven five-day periods, and during each of these periods he was on definite food and some drug intake. The food, urine, stool, and blood analyses at each period were tabulated. These analyses are not yet all completed but the calcium is slightly elevated, the phosphorus normal, and the cholesterol decidedly low, being at one time 95 milligrams. His

icterus index had always been elevated into the zone of latent jaundice, but none of these findings can as yet be correlated, neither can it be said that there was any clinical improvement. However, the patient was put on a high calcium diet and given 50 drops of viosterol per day.

X-ray Examination.—The bones of the skull and all bones except the radius and ulna in both arms and the bones of the spine and pelvis, showed the characteristic changes of osteitis deformans.

This case seems to be of particular interest in that the onset of the disease was at the age of 34 or, at the most, 34½ years, which is rather young for osteitis deformans.

Case 14 The patient, M C, was a white female, 54 years of age. At the age of 50, she had complained of pain in her left hip, which persisted and became worse. It was diagnosed as arthritis. No results were obtained from autogenous vaccine or by diathermy. One year previous to the present examination she was said to have had tuberculosis of the hip, but the present X-ray examination revealed typical changes of osteitis deformans in the bones of the pelvis and left femur. There were also slight changes in the bones of the skull.

Her blood calcium was 11.2. Her Wassermann test was negative, as were the other tests.

On Feb 28, 1930, the patient was put on viosterol, drops 25, three times daily, calcium lactate, gr. 60, twice daily, tomato juice, 6 ounces. This therapy has been continued with the exception, as in other cases in which calcium has irritated the kidneys and bladder, of a period during which milk is alternated with the calcium. The patient has shown definite, though not very marked, improvement in her clinical symptoms. Later X-ray examinations show no change in the bones.

Case 15 S D M, white male, 56 years of age, is not a very intelligent type. He

gave a history of pain of three weeks' duration in his right shoulder, but showed no noticeable change in the size of his head. No other history could be obtained on close questioning. From the appearance of the X-ray films of the right shoulder, a well-established osteitis deformans was found to be present, which certainly had existed for longer than three weeks. Changes also were present in the skull and left humerus, and extensive involvement in the dorsal and lumbar spine, as well as in the bones of the pelvis and the heads and trochanters of the femurs. Slightly less advanced changes showed in the tibias. Therefore, with these X-ray findings, it was apparent that the patient had had this disease for some time.

Blood calcium, 9.8, phosphorus, 3.5, cholesterol, 1.65

June 9, 1930.—He was given viosterol, milk, and tomato juice.

Aug. 1.—The patient returned, feeling much better, although he still had some pain in the arm. Calcium lactate with viosterol was prescribed twice a day instead of three times.

Aug. 22.—The patient had considerable pain in the right shoulder and arm. The pain diminished but stiffness and pain in the back of the neck were present and the patient could not sleep. The régime was continued, with heating and massage to the neck, and luminal, one-half grain, was prescribed for pain.

Sept. 16.—The patient still complained of much pain. The régime was continued with the addition of sodium acid phosphate.

Oct. 1.—Considerable pain and stiffness were complained of. Viosterol, 30 drops, was prescribed instead of calcium lactate.

Oct. 8.—Sodium phosphate was discontinued, otherwise the same régime was adhered to.

Oct. 15.—The patient felt fairly well, the pain was considerably lessened, though

usually it became much worse in warm weather. The régime was continued, except the man was ordered to take clinradol instead of viosterol.

Oct. 21.—The patient was fairly well and felt much better, although he slept poorly. Clinradol was continued.

Oct. 27.—The patient stopped smoking for ten days and the régime was continued. Complaint was made of severe pain and burning in the left shoulder. Blood sugar test was made on Oct. 29, showing 112 mg of sugar.

Nov. 3.—One glass of tomato juice and four glasses of milk per day were ordered. The pain in the left shoulder was still severe.

Nov. 10.—Tomato juice was discontinued and acid phosphate substituted.

Nov. 17.—Tomato juice, calcium lactate, and clinradol were ordered. As sodium acid phosphate made the patient ill, it was discontinued. Complaint was still made of pain in the arm.

He is being continued on treatment.

Case 16 H. B., a white woman, 58 years of age, was admitted to the hospital in December, 1927. She complained of difficulty in walking, had assumed a waddling gait for one and one-half years, and had experienced a feeling of heaviness in the lower limbs for the year preceding examination, with shortness of breath and general weakness.

The family history was negative as was the past history, except for the usual childhood diseases. The patient said that in 1907 she had had an exophthalmic goiter which had been cured by medication and X-ray therapy.

Present Illness.—The patient had been in good health until three years before admission, when she first noticed a slight bowing of the legs, although this did not trouble her in any way. As a child she had not been bow-legged. The bowing gradually increased. Two and one-half years before the present

examination, she noticed stiffness in her legs which usually was present after considerable walking. There was no pain in her legs. This condition continued until about one and one-half years previous to examination, when she had difficulty in walking. She noticed about this same period that she had to get larger sized hats. Otherwise no deformities or pathologic fractures were present and the patient seemed in fairly good health.

X-ray Examination—Several examinations made in 1927 showed very typical changes of osteitis deformans involving the skull, the dorsal and lumbar spine, entire right tibia and head of the left, the pelvis, both femurs, and the heads of the humerus on both sides.

Calcium lactate and acid sodium phosphate were prescribed and the patient's blood calcium is being followed carefully. She has steadily improved on this treatment, has been able to return to work, and is feeling fairly well. The deformities remain the same.

Case 17 C S, white male, 73 years of age, was admitted to the hospital first in 1908 for urinary retention, rectal abscess, and ulceration of the rectum. The abscess was incised. He was re-admitted on Aug 23, 1930, after being struck by a vehicle, when he sustained a laceration of the forehead and contusion of right eye, and was rendered unconscious. After recovery from unconsciousness the man was found to be moderately deaf. He had an unusually large head, the sternum was prominent, and the arteries hard and thickened. Knee jerks were absent. In the phalangeal joints of the hands there was definite enlargement, and the other bones were slightly thickened, with some bowing.

X-ray Examination—The skull, spine, humeri, shoulders, ulnas, tibias, fibulas, and pelvis exhibited the characteristic changes of advanced osteitis deformans. The

femoral and iliac arteries showed extensive calcification, also extensive hypertrophic osteo-arthritis was present.

This patient was treated with calcium lactate and viosterol for a short time and then trace of him was lost.

Case 18 V K, a white man of 39 years, was admitted to the hospital on Dec. 13, 1917, complaining of recurrent fracture of the lower right leg. He said that his shins had always bulged as do the shins of his father and brothers. The bowing had increased markedly in the few years preceding admission to the hospital. About two and one-half or three months earlier the patient had fractured the lower right leg by falling. He was treated and put in plaster, which was removed just a few days before admission. The patient was walking downstairs when he stumbled and his right leg crumpled up under him.

The man's past history is negative except for previous fractures. He had had five blood tests, which were always negative, for specific trouble.

X-ray Examination—Radiograms showed a pathologic fracture due to a very typical change of osteitis deformans.

No further examination was made of this patient and he was treated for the condition. One feels that, though no skull films were made, the changes are in all probability due to osteitis deformans. This is another case in which osteitis fibrosa cystica, particularly in view of the patient's age, cannot be eliminated.

Case 19 Mrs R, white female, 61 years of age. About six years before the present examination, she noted pain and stiffness of her right knee. She recollects back over fifteen years and said that at that time she had had some trouble with her back. She did not know what this was except that it was painful and caused limitation of motion. Her other history and physical findings were negative except for an increase in

pain and disability, with increase in the bowing of her legs. She had also noted that her head was becoming larger. The blood calcium was 9.6.

Treatment was first started on Dec. 17, 1927, being the same as in the other cases, and was continued up to Oct. 27, 1930.

Throughout her illness this patient complained of severe headaches. At times the calcium and viosterol medications relieved them, but at other times nothing was effective except nitroglycerin. This was given in an attempt to reduce her blood pressure on the theory that her headaches might be caused by a dilated blood vessel at the base of the skull where the blood vessels pass into the cranial cavity through the opening which is contracted by encroachment in the foramina by an increase in bony deposits. This medication has been quite effectual.

The patient's condition has remained stationary, except that when she is put on a high calcium diet she feels well and has no pains except the headaches and is able to do a certain amount of her housework. However, as soon as she is on a low calcium diet she becomes much worse.

Radiographs made during the period from 1927 almost to date (November, 1930) have shown practically no change, being typical at all examinations of osteitis deformans.

Case 20 I. L., white, housewife, aged 62 years. The patient complained of pain in leg, and bowing, which had been present for several years. The onset of disease was apparent eight years preceding this examination, with pain in her leg. Three or four years before examination, she had noted a beginning enlargement of her head and a little later beginning bowing of her tibias. For two years there had been pain in her leg and occasionally pain in the arms but no headaches. There had been diminished hearing for two or three years before admission to the hospital, with general weak-

ness and considerable difficulty in walking. X-ray findings of the skull, pelvis, spine, and long bones were very typical of osteitis deformans.

Oct. 7, 1930.—The patient was given viosterol, drops 30, tomato juice and milk, three glasses of each every day.

Oct. 15.—The patient felt much better, the weakness was lessened, the pains diminished, and she said she felt more "limber." Medication was continued.

Oct. 28.—Calcium lactate was alternated with the milk every two weeks. The woman experienced pain in her back and when walking, but otherwise was considerably better and able to do her housework.

Nov. 17.—There were slight pains in the arms and legs, however, the patient was able to walk and to do her housework. The régime was continued except that clinradol was substituted for viosterol.

The patient has continued in fair health up to the date of this report.

Case 21 J. S., a white man, 67 years of age, was admitted to the hospital on Aug. 3, 1930, complaining of diabetes and of urinary symptoms which had been present for three months. For two years preceding admission he had noted enlargement in the size of his head and weakness of the legs. Three months before examination, the patient had noted frequency of urination, increase in appetite, and marked thirst. He had lost 24 pounds during the six months preceding examination.

About two years earlier, or more, the patient's femur had become "lopsided," which the patient claimed was a sudden happening (?) The change was almost as marked then as it was at examination. Shortly after this the patient complained that his legs were heavy and weak, the right more so than the left. He had been told two years earlier that he had Paget's disease.

The family history was negative. The patient had always been in good health ex-

cept for an attack of lumbago, two years before hospitalization. He had a chronic infection in both ears and had been deaf for over twenty years.

Physical Examination—The head was of peculiar shape, sloping in the frontal regions. The eyes, nose, and mouth were negative, as were the neck, lungs, and heart. The abdomen was soft, exhibiting no rigidity. The lower extremities showed definite bowing of the femurs and tibias, the arms showed no deformities though there was some thickening of the humerus on deep palpation. Knee jerks were absent.

X-ray Examination—Examination made on Aug 22, 1930, showed the skull, right humerus, left humerus, and both femurs and tibias to have undergone the typical changes of osteitis deformans.

Further examination showed disturbances of the trabeculae of the lumbar spine and bones of the pelvis, with some evidence of cystic formation and bizarre deposits of calcium so characteristic of osteitis deformans. The patient's blood calcium varied between 0.5 and 1.0. There was no Bence-Jones protein in the urine.

The patient remained in the hospital until Sept 6, 1930. Calcium lactate and viosterol were prescribed, to be taken in a similar manner to the other cases. He was still being treated late in 1930 and showed then some slight improvement.

Case 22 Mrs K B, a white woman, 50 years of age, was admitted to the hospital with a chief complaint of swelling and pain in the right leg and marked headaches which had been present for two or three years. Her physical examination was negative except for some apparent thickening of the bones and a slight bowing of the tibia, and the radiographs showed the typical changes of osteitis deformans. Her blood calcium was 12.3. The other examinations were entirely negative.

May 22, 1928.—The patient was given

calcium lactate, 40 grains, twice a day, calcium hyperphosphate, 30 grains, three times a day, before meals. She returned one week later, saying the pains in her legs were much lessened and the headaches had entirely disappeared. Medication was continued and oscodal added.

June 19, 1928.—The blood calcium was 10.4 and the sugar 96. Medication was continued but, because of nausea, the oscodal was dropped. One month later the blood calcium was 10.8. Calcium hyperphosphate was continued and other medication stopped.

Nov 20, 1928.—The patient complained of "sticking pains" everywhere, and weakness on exertion. Strychnine sulphate, 1/30 gr three times a day, calcium lactate, and tomato juice were given.

May 21, 1929.—Medication was continued and the patient improved steadily.

Nov 12, 1929.—The patient complained of pain in the head and neck and tenderness in the right leg. She had gained in weight, but had not been taking medication for two months.

Dec 10, 1929.—The patient felt much better. The headaches, pain in the leg, and stiffness were no longer apparent but she experienced considerable effort in moving about. Viosterol, gr 30, was given twice daily and other medication was discontinued.

July 1, 1930.—But for slight pain in the right leg, the patient felt very well. Calcium lactate was given, and viosterol was continued, alternated with milk and tomato juice every other day. The patient's progress was satisfactory.

Case 23 J G, a white male, 50 years of age, was admitted to the hospital in June, 1922, entering with a history of fracture of the femur sustained by a twisting motion and not by direct violence. The injury was seemingly trivial but resulted in a fracture.

X-ray Examination—Examination showed a fracture of the femur accompa-

nied by the changes typical of osteitis deformans. The fracture healed without difficulty.

The patient was re-admitted in March, 1930. The history between the previous and present admissions was of no significance except that the patient complained of bone pains and disability when walking. He was unable to stand straight. He also had had considerable pain in his back and had noted stooping and decrease in his stature. These changes had been very gradual during the four years preceding the present examination. Eight days earlier he had awakened with severe pain, which lasted for two hours, in the hip and lumbar region. This severe pain soon subsided but a continual ache persisted for that day. No numbness or other changes were noted except deafness in the right ear.

Physical Examination.—The patient was a fairly well-nourished individual of slightly vacant facial appearance and stooped posture. He had a very large head and his face was slightly triangular. The legs showed no apparent bowing, the back was slightly bent, the sternum prominent, the lumbar region flattened, and the teeth rather poor. The neck showed no glandular enlargements. The heart examination was negative, the lungs, clear, the abdomen, negative. All reflexes were present.

X-ray Examination.—Radiographs made on March 4, 1930, showed the bones of the lumbar spine, hip joints, and pelvis to have that lacy appearance of bone with bizarre calcific deposits scattered throughout, and some cystic formation, which is typical of osteitis deformans. The old healed portion of the upper part of the shaft of the femur was clearly seen. There was also bizarre arrangement of the bone trabeculae.

All laboratory tests were negative. The patient had low blood calcium content and was referred to Dr. Bernheim's clinic for

Case 24 Mrs. T., aged 50 years, who was referred to the hospital for radiographic examination, had been a missionary in the Philippine Islands for years. For a considerable period of time she had suffered from what she termed "rheumatism" for which she received varied medication without relief. A complete history of this case was not secured owing to the fact that the patient was referred for radiographs only and left for the Philippine Islands shortly after the examination. She has since been heard from through her physician, who states that her condition is becoming progressively worse. Her pains are about the same, but her disability is increasing and she finds walking correspondingly difficult.

X-ray Examination.—The films showed changes in the bone to be a fibrous cystic degeneration. The bone trabeculae were arranged in longitudinal bundles, and were mottled by areas of decreased density, indicating absorption of calcium, and also a suggestion of beginning cystic formation. The rather unusual feature in this case was that the hands showed an involvement in one of the first metacarpal bones. The skull showed no evidence of the changes of Paget's disease.

Due entirely to the lack of involvement of the skull, this might be classed with Case 26 as a doubtful case of osteitis fibrosa cystica of the generalized type; however, the authors do not feel that this lack excludes Paget's disease. Due to the patient's age and the fact that her symptoms have been present for not more than six or eight years, it would seem that this is a case of Paget's disease without involvement of the skull.

Case 25 F. D., aged 41 years, while walking fast, fell over a low table, causing a fracture of the left femur. For about six months previous to the injury he had noted in the right leg a slight pain in the

localize, he thought it was probably rheumatic. The pain seemed to disappear when he exercised. Previous to the injury he had felt tired and slightly under par, he also had had continuous headaches for some six months. There was no family history of similar pains, the father died of rheumatism, the mother, of shock. The patient had had uniformly good health save for childhood diseases and occasional attacks of tonsillitis. His personal history was irrelevant.

The patient presented slight bowing of both legs, particularly of the femurs, and since he had sustained the fracture he had had to walk with a cane. His left knee was slightly limited in motion but there was no stiffness of the hip. Apparently his height had not undergone change. His skull showed slight thickening over the occipital protuberance and was rather large and square in appearance, but the face was fat, so that it did not have the typical triangular appearance.

X-ray Examination.—Radiographs revealed marked osteitis of the left femur, with the pathologic fracture, in addition, the bones of the pelvis and the upper half of the right femur were similarly involved. Also, changes in the lumbar spine and the posterior portion of the skull in the occipital and occipitoparietal regions showed definite thickness, with abnormal distribution of the trabeculae. In the parietal regions there was a suggestion of a beginning typical appearance, as described by Baetjer. These findings were interpreted as due to Paget's disease.

Summary.—This case shows essentially the same X-ray findings as were noted in the following case, but here the skull did show changes, so that again the question arises as to which classification should be applied. One school would claim that this was unquestionably a case of Paget's disease

because of the involvement of the skull. The other school would claim that there is no case of true osteitis deformans without the involvement of the skull, yet the changes in the long bones, the pelvis, and the spine in this case and the one following are very similar.

Case 26. H. P., aged 52 years, was admitted to the hospital on July 13, 1915. On the evening of admission the patient was standing on a window-seat 18 inches above the level of the floor. He was holding a heavy curtain, and, in attempting to step from the window-seat to the floor, his foot slipped and he fell to the floor, from which he found it impossible to rise. He had very little pain but knew from the deformity that his thigh was broken. The patient had always felt that the right leg was not so strong as the left, when he was a child he had noticed that he could not do things with the right leg which he could with the left. When he was about 30 years of age, he had had an accident, with resulting contusion of the right leg. Later two abscesses developed near the tibia, which necessitated treatment for two months, during most of which time he was confined to bed. The patient said that for some seven weeks previous to admission he had had rheumatism and pain in the bone in his right thigh, the pain being especially severe in the anterior muscles over the middle third of the thigh. The pain was made better by resting and was less severe at night. There was also more pronounced weakness in the right thigh than previously. He walked with a slight limp, and used a cane because he felt the leg could not support him. The past history was otherwise negative and the family history was irrelevant.

Physical Examination.—The examination was negative except for the right leg, which showed no evidence of contusion or external violence. The limb was held in external

rotation. There was marked anterior bowing just above the middle of the thigh, and extreme tenderness in this region. A mass was felt, apparently the upper fragment of the fracture, which was palpable anteriorly. A corresponding mass was felt posteriorly. There was crepitus on motion. The right leg was one inch shorter than the left.

X-ray Examination.—Examination showed pathologic fracture of the right femur, with bony changes indicating an osteitis. These changes consisted in a disturbance of the bone trabeculae, osteoporosis, and cystic formation in the cortex and medulla, with some evidence of periosteal bone production and a widening and bending of the bone.

The patient was afebrile throughout the course of his convalescence from the fracture. His urine was practically always normal and his blood count showed nothing unusual. The fracture healed satisfactorily and the patient was discharged as cured on Nov 4, 1915.

On Jan 1, 1916, the patient was readmitted with the following history. A few minutes before admission, while he was getting off a train, his crutch slipped, and he fell a distance of two steps, striking his right heel with considerable force. His thigh became very painful at the site of the old injury and there was an apparent deformity. On admission, the deformity and swelling were clearly seen, and tenderness was apparent. The history was as recounted above on the previous admission.

X-ray Examination.—At this time the films showed a recent pathologic fracture at or near the site of the previous fracture, the changes being the same as in the previous examination except that the condition seemed still more advanced and was complicated by callus formation about the old fracture. Nothing else of interest was found in the history. The patient was dis-

charged on February 9 with a firmly united fracture.

Oct 17, 1916, he was again admitted to the hospital with another fracture of the right femur near the site of the two previous pathologic fractures. There was nothing further of interest in his history except that this fracture was sustained, as in the previous instances, with a minimum amount of trauma, namely, that he missed one step and the resulting jar caused the injury. The X-ray examination at this time showed distinct advance in the pathologic changes in the bone, and the left tibia showed the changes noted in Paget's disease. His blood calcium was never estimated. The blood count was normal, as was the urine analysis. The blood pressure was within normal limits for a man of his age.

Summary.—This is one of those cases in which it is a question as to what classification is to be applied. The X-ray examination and the patient's history show an osteitis involving numerous bones of the body. The condition is progressive, as the patient was again examined roentgenographically in February, 1927.

This case, however, has never had involvement of the skull. Also, the patient has given a history of slight disability in his right thigh since childhood, including abscesses on the leg. The question arises: Is this case one of so-called osteitis fibrosa which the patient had for some forty years before sustaining pathologic fractures and in which the skull has never been involved? On the other hand, are we to class this as a case of osteitis deformans without involvement of the skull, and are we to consider that the previous disability and weakness of the right thigh and the previous infection were in no way related to the present bone disease? It seems that this case is one of those that simply cry out for further investigation.

RADIATION TREATMENT OF UTERINE HEMORRHAGE OF BENIGN ORIGIN¹

By J H BRIDENBAUGH, M D (Arthur J BILLINGS,

Movius, M D, and J H Bridenbaugh, M D),
BILLINGS,
MONTANA

ELEVEN years ago last January, I began to treat certain selected cases of uterine hemorrhage by radiologic methods. The early cases responded in such a uniformly satisfactory manner that in a short time we were using radiation in a fairly large number of cases that had formerly required major surgical operation for relief. In this paper I wish to present briefly a study of some of the difficulties encountered, the methods used, and an analysis of the end-results of the whole series. Due to the fact that the management varies a great deal with the type of case, I wish to divide them into three groups.

1 Young women under 35 without tumor or other demonstrable pelvic disease who resisted conservative treatment and continued to bleed excessively. In this group there are 10 cases the records of which are complete. This type of patient was studied carefully, medical measures and curettage were tried before radium was advised, and it was only in the exceptional case that we found the use of radiation necessary. The treatment of this type of case consisted of the intra-uterine application of small doses of radium—200 to 400 mg.-hrs being sufficient. The results have been uniformly good. All patients have been promptly relieved of their excessive bleeding and there have been no unpleasant complications. One patient returned after a period of five years with excessive bleeding, and she is at present under observation.

2 The second group includes the patients who were near or past the usual age for the menopause, who had no demonstrable tumor or inflammatory disease to account for their hemorrhage, but who continued to bleed excessively in spite of con-

servative medical management. Their condition is commonly styled hemorrhage of the menopause and is said to be due to fibroid of the uterus or metritis or endometritis. In this group of patients there are 31 cases, with an age range of from 40 to 57 years. The treatment of this type of case differs considerably from the others, since the only object of treatment is control of the hemorrhage. Small doses of radiation are usually all that is needed, and X-rays and radium act equally well. The average dosage of radium is 1,000 milligram-hours. One cycle of X-ray therapy is usually sufficient. The following case was exceptional, and the only one in this group that presented any unusual difficulties.

Mrs H, age 57 years, consulted me on October 26, 1926.

History.—For several years her periods had been irregular. Twenty-two months previous to examination she began to bleed, and continued to flow in small amounts. She complained of pain in the back and legs. She gave no history of other illness except an occasional attack of asthma. She had never been pregnant.

Physical examination, aside from evidence of a considerable degree of anemia, was quite negative. Vaginal examination disclosed a retroverted uterus, but normal in size. There was no other pathology found in the pelvis. The cervix appeared normal. X-ray therapy was advised and monthly doses of moderate voltage X-ray were administered. The bleeding promptly ceased but recurred in small amounts at irregular intervals.

Her subsequent history reads as follows: "March 1, 1927 (five months after starting treatment)—Had a slight hemorrhage a few days ago. Has had very little bleeding the past two months. Examination negative."

¹Read before the Cascade County Medical Society of Great Falls, Montana March 21, 1931

"August 10, 1927—Has brownish discharge, slight bleeding at irregular intervals
Examination negative

"October 28, 1927—Slight bleeding past few days

"January 17, 1928—During past month the patient has had considerable bleeding. Curettage and radium treatments were advised. Pathologic report, endometritis. Results, complete cessation of bleeding."

This patient was quite well for one year following X-ray therapy except for occasional slight bleeding. She declined further treatment until hemorrhage again became severe. The end-result was entirely satisfactory and she has remained well to date.

3 The third group is composed of the fibromyomas and in this group there is still room for study and discussion as to the best mode of treatment. In January, 1931, Dr E H Zweifel, of Munich, in his Mayo Foundation Lecture entitled "Treatment of Fibromyoma by Roentgen Rays," says "Ten years ago when I wrote a paper on this subject, I thought the discussion practically finished, but it is not, even yet, and further experience has led me to open the discussion once more." He states as his conclusions that irradiation of myomas is the treatment of choice. With careful diagnosis and selection of cases, it presents the least risky way to recovery.

Francis Carter Wood, in the *Journal of the American Medical Association*, March 1, 1930, says "Many uncomplicated fibromyomas are still removed surgically which could perfectly well be treated by X-rays. The advantages of X-rays are lack of risk, simplicity of treatment, certainty of results, and low cost to patient."

Certain cases are undoubtedly best treated by surgical operation, while others can be definitely placed in the group in which radiation is the treatment of choice. In the borderline cases in which the complete diagnosis is in doubt, there will always be a divergence of opinion as to the best form

of therapy. Such divergence of opinion is at the present time great. One prominent gynecologist states that the treatment of fibromyomas by X-rays is useless and exercises a harmful effect on the general endocrine activity and metabolism. He recommends panhysterectomy in all cases, but admits a mortality of 5 per cent. Certain German gynecologists irradiate a very large percentage of their cases. A prominent French authority (Beclère) made the statement that a myoma of the uterus always constitutes an indication for radiation therapy. During a seven-year period, at St Luke's Hospital, New York City, 1,443 myomas were operated upon. During the same period, 20 cases were referred to the Radiotherapeutic Department for treatment. In the gynecologic service of the University of Pennsylvania, during a five-year period, 681 cases were treated. Of these, 428 were treated by surgery, and 253 by radiation. Our records show a total of 288 cases treated since we began to use radiation treatment. During this same period, 20 uterine fibromyomas were operated upon by Dr Movius. There has been no mortality in this entire group.

In deciding which type of case is best operated on, it is generally agreed that very large, necrotic, or calcified tumors are best treated by surgical removal. Pedunculated and submucous growths are at times resistant to radiation and may constitute an indication for surgery. Tumors occurring in comparatively young women, in whom it is possible to preserve the major portion of the uterus, are best treated by surgery.

Less than two years ago I was asked see a patient who had a large fibroid. She was about 40 years of age, had been married only a short time, and was very anxious to have a child. I advised operation, which was performed. This patient is now near term and has every indication that her pregnancy will terminate successfully. Radiation would almost certainly have destroyed her reproductive function.

Mention may be made at this time of one patient who came under my care in 1927. The woman, who was 35 years of age, had a fibroid the size of a small orange, and had had severe hemorrhages. She was given two moderate dosage X-ray treatments which controlled her bleeding. Last April (three years after treatment) she was referred to me by the late Dr Thuerer for examination of her abdomen to determine the nature of a large abdominal tumor. X-ray examination disclosed the presence of three fetuses. Unfortunately she aborted at approximately the fifth month. No evidence of any fibroid tumor could be found.

The question of a possible malignant growth being present in addition to the myoma is one that must have due consideration. Carcinoma of the body of the uterus is best treated by complete hysterectomy, and the radiation commonly used for fibromyoma will have little or no effect on carcinoma. The incidence of carcinoma complicating myoma as drawn from extensive pathologic records is about 0.5 per cent. It is our experience that carcinoma can usually be excluded by a careful history, as the bleeding from carcinoma is as a rule slight, irregular in character, and accompanied by a watery discharge. Diagnostic curettage is used only in doubtful cases and followed immediately by radium treatment. We have not, to our knowledge, treated any cases of carcinoma under a mistaken diagnosis of myoma. Sarcoma complicates myoma in less than 1 per cent of all cases examined pathologically, which is considerably less than the average operative mortality from hysterectomy. We have had no experience with this condition. Of the 268 cases treated, 22 were between 50 and 60 years of age, 202 between 40 and 50, and 67 under 40. Of these, 24 had tumors classed as very large, extending well up into the abdomen, in several instances reaching as high as the umbilicus, 244 had intrapelvic myomas of which 162 were classed as large,

moderate, practically filling the pelvis, and 82 were small, about the size of an orange. Symptoms, aside from hemorrhage, which was present in most cases, were pain, pelvic and abdominal, in 41 cases, backache in 50, shortness of breath in 10, severe headache in 30. In two patients, pressure on the bladder was sufficient to interfere with urination. In that they did not complete the treatment as outlined and went elsewhere for operative treatment, 6 patients are classed as incomplete. One patient, whose history is as follows, was a failure as far as radiation treatment was concerned.

Mrs J., age 42 years, complained of profuse menstruation which had begun 18 months previous to examination. The flow had lasted from 8 to 14 days, and at the time she came for treatment she had been flowing for three weeks. On examination, a myoma the size of an orange was found. X-ray treatments were given in October, November, and December, 1927, and January, 1928, with very little effect. She was advised to have a curettage and intra-uterine radium treatment, which were done, but the bleeding continued, and hysterectomy was finally performed. The examination of the uterus showed a small submucous fibroid about the size of an egg, very hard and fibrous in character, which apparently acted as a foreign body. This patient made an uneventful recovery.

Another patient who was resistant to X-ray therapy was Mrs C., referred by Dr Armstrong. She was a woman past 50 years with a tumor that nearly filled the pelvis. Her periods were heavy, and she had a moderate degree of anemia. X-ray therapy was started in January, 1926, twelve X-ray treatments being given during the year. The excessive bleeding promptly responded to the treatment, but she continued to menstruate a small amount. At the end of the year, I urged diagnostic curettage and radium treatment but these were declined. Dr Armstrong said the tumor had dis-

"August 10, 1927—Has brownish discharge, slight bleeding at irregular intervals
Examination negative

"October 28, 1927—Slight bleeding past few days

"January 17, 1928—During past month the patient has had considerable bleeding
Curettage and radium treatments were advised
Pathologic report, endometritis
Results, complete cessation of bleeding"

This patient was quite well for one year following X-ray therapy except for occasional slight bleeding. She declined further treatment until hemorrhage again became severe. The end-result was entirely satisfactory and she has remained well to date.

3 The third group is composed of the fibromyomas and in this group there is still room for study and discussion as to the best mode of treatment. In January, 1931, Dr E H Zweifel, of Munich, in his Mayo Foundation Lecture entitled "Treatment of Fibromyoma by Roentgen Rays," says "Ten years ago when I wrote a paper on this subject, I thought the discussion practically finished, but it is not, even yet, and further experience has led me to open the discussion once more." He states as his conclusions that irradiation of myomas is the treatment of choice. With careful diagnosis and selection of cases, it presents the least risky way to recovery.

Francis Carter Wood, in the *Journal of the American Medical Association*, March 1, 1930, says "Many uncomplicated fibromyomas are still removed surgically which could perfectly well be treated by X-rays. The advantages of X-rays are lack of risk, simplicity of treatment, certainty of results, and low cost to patient."

Certain cases are undoubtedly best treated by surgical operation, while others can be definitely placed in the group in which radiation is the treatment of choice. In the borderline cases in which the complete diagnosis is in doubt, there will always be a divergence of opinion as to the best form

of therapy. Such divergence of opinion is at the present time great. One prominent gynecologist states that the treatment of fibromyomas by X-rays is useless and exercises a harmful effect on the general endocrine activity and metabolism. He recommends panhysterectomy in all cases, but admits a mortality of 5 per cent. Certain German gynecologists irradiate a very large percentage of their cases. A prominent French authority (Beclère) made the statement that a myoma of the uterus always constitutes an indication for radiation therapy. During a seven-year period, at St. Luke's Hospital, New York City, 1,443 myomas were operated upon. During the same period, 20 cases were referred to the Radiotherapeutic Department for treatment. In the gynecologic service of the University of Pennsylvania, during a five-year period, 681 cases were treated. Of these, 428 were treated by surgery, and 253 by radiation. Our records show a total of 288 cases treated since we began to use radiation treatment. During this same period, 20 uterine fibromyomas were operated upon by Dr Movius. There has been no mortality in this entire group.

In deciding which type of case is best operated on, it is generally agreed that very large, necrotic, or calcified tumors are best treated by surgical removal. Pedunculated and submucous growths are at times resistant to radiation and may constitute an indication for surgery. Tumors occurring in comparatively young women, in whom it is possible to preserve the major portion of the uterus, are best treated by surgery.

Less than two years ago I was asked see a patient who had a large fibroid. She was about 40 years of age, had been married only a short time, and was very anxious to have a child. I advised operation, which was performed. This patient is now near term and has every indication that her pregnancy will terminate successfully. Radiation would almost certainly have destroyed her reproductive function.

RADIOTHERAPY WITH SMALL QUANTITIES OF RADIUM

A PRACTICAL TECHNIC

By PAUL O SNOKE, M.D., LANCASTER, PENNSYLVANIA

From the X-ray Department of the Lancaster General Hospital

THOSE radiologists not working in the large centers frequently feel that the practical and clinical aspects of radiotherapy are being forgotten by those concerned with scientific research. The practising radiologist is concerned with clinical results and the manner in which they may be obtained with his small quantity of radium. We deem it timely to correlate the highly

sylvania, with a different technic, is securing. It would seem that the amount of radium available has very little to do with the results, but, rather, that the manner of its application is all-important.

We have available at the Lancaster General Hospital 75 milligrams of radium, these limited resources making it necessary to prolong the treatment time—not a disadvantage, as Regaud has shown. We do not use in every case the heavy filtration he advocates, but attempt to vary it, increasing the filtration as the depth of the lesion increases.

If we, as practical radiologists, can select a technic using small quantities efficiently, we can achieve as brilliant results as have been obtained in the centers devoted to scientific investigation, with the splendid advantage of individualization. We venture to report our methods in the hope that they may aid in the adaptation of scientific fact to practical therapy.

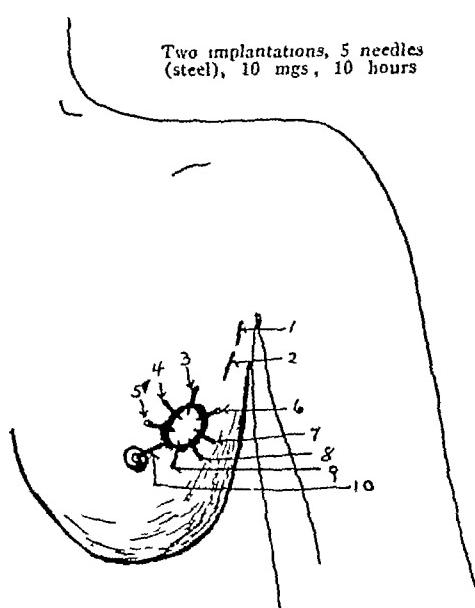

Fig. 1 Mapping of carcinoma of the left breast, 4.5 X 3 X 3 centimeters

scientific with the practical aspects of the problem. Unfortunately in many reports the statistical data so hide the technic of treatment that, though one reads his periodicals, he still fails to appreciate the necessary details.

If we study these periodicals we find that Forssell (1) and Berven and Heyman (2), in Stockholm, and Bowing (3), at the Mayo Clinic, are achieving the same percentage of five-year cures in carcinoma of the cervix that Norris (4), at the University of Penn-

INTERSTITIAL RADIATION

Before undertaking any radium implantation the lesion is mapped and measured (Fig. 1). From a sketch made at this time the location of each needle is predetermined, also fatty tissue and bony structures are considered. The needles, measuring 1.5 mm X 2.7 cm, with a wall thickness of 0.4 mm steel, are so arranged that their points are 1.2 cm apart after insertion. They are implanted in one plane unless the lesion is so thick that two planes are required. This is rarely the case, for we can resort to radial implantation, using the tumor as a hemisphere or sphere, pointing the needles toward the center.

peared and he saw no reason for further treatment. This patient's menstruation ceased entirely after a few months and she has since remained well.

There have been two cases in which the size of the tumor has not been satisfactorily reduced and operation has been performed for removal of a large tumor, after the hemorrhage had been controlled and the patient's general condition markedly improved.

In order to meet the needs of the individual patient, the methods of treating myoma by radiation are necessarily varied. Severe bleeding usually calls for a moderate dose of radium as this will almost invariably cause a prompt arrest of the hemorrhage. When the tumor is large it is necessary to follow the radium treatment with moderate doses of X-rays at intervals of from ten days to two or three weeks, over a period of about three months or longer, in order to secure a satisfactory reduction in the tumor. Until 1928, a large portion of my cases were treated with an old type 10-inch machine which I have since found will deliver only 100 KV at the altitude in Billings. A few cases have been treated with voltages as high as 200 KV and filters of 0.5 mm copper. There is apparently very little advantage in the larger doses and higher voltages as far as the tumor is concerned and the patient does not tolerate the higher voltage so well. My present technic consists of 150 KV, 0.25 mm Cu, about 300 r applied alternately to front and back every ten days. I usually give eight or more treatments. This plan of treatment causes the patient to experience little or no reaction or inconvenience of any kind. Patients who live a long distance from Billings are usually advised to take 1,600 mg-hrs of radium in order to minimize the number of trips necessary to secure satisfactory results. Patients are re-examined after six weeks of treatment, and at monthly intervals

thereafter. Treatment is continued until the tumor has been reduced at least 50 per cent in size, and longer, if the size of the tumor appears to be causing symptoms.

That a gradual reduction of the size of the tumor goes on for a long time after treatment is discontinued has been repeatedly proved by our own observation. One of my early cases was a striking illustration of this. This patient had a large, hard fibroid reaching nearly to the umbilicus. Treatment promptly stopped hemorrhage and the tumor became smaller. After about seven months of treatment the patient was practically symptom-free. Reduction in the size of the tumor was estimated at about 40 per cent. The patient moved away at this time but she returned for observation after one year. During this year she had had no treatment. Examination at this time showed a complete disappearance of the tumor.

Skin reactions are few, and cause little or no trouble. Some patients complain of nausea, but this is less since we have shortened our treatment time. The usual nervous manifestations of the climacteric are to be expected, apparently differing little or none from those seen at the natural menopause. Many patients ask the question, "Won't this treatment make me an old woman?" My reply is that, on the contrary, it is the best method we have of rejuvenation.

SUMMARY

A total of 309 cases of uterine bleeding have been subjected to radiation treatment. One case resulted in complete failure. In two cases the bleeding was controlled, but subsequent operation was necessary for removal of the tumor. Six cases discontinued treatment before a complete series had been administered. In 300 cases a satisfactory result has been achieved.

RADIOTHERAPY WITH SMALL QUANTITIES OF RADIUM

A PRACTICAL TECHNIC

By PAUL O SNOKE, M.D., LANCASTER, PENNSYLVANIA

From the X-ray Department of the Lancaster General Hospital

THOSE radiologists not working in the large centers frequently feel that the practical and clinical aspects of radiotherapy are being forgotten by those concerned with scientific research. The practising radiologist is concerned with clinical results and the manner in which they may be obtained with his small quantity of radium. We deem it timely to correlate the highly

scientific with the practical aspects of the problem. Unfortunately in many reports the statistical data so hide the technic of treatment that, though one reads his periodicals, he still fails to appreciate the necessary details.

If we study these periodicals we find that Forssell (1) and Berven and Heyman (2), in Stockholm, and Bowing (3), at the Mayo Clinic, are achieving the same percentage of five-year cures in carcinoma of the cervix that Norris (4), at the University of Penn-

INTERSTITIAL RADIATION

Before undertaking any radium implantation the lesion is mapped and measured (Fig. 1). From a sketch made at this time the location of each needle is predetermined, also fatty tissue and bony structures are considered. The needles, measuring 1.5 mm × 2.7 cm, with a wall thickness of 0.4 mm steel, are so arranged that their points are 1.2 cm apart after insertion. They are implanted in one plane unless the lesion is so thick that two planes are required. This is rarely the case, for we can resort to radial implantation, using the tumor as a hemisphere or sphere, pointing the needles toward the center.

The patient is given a general anesthetic, preferably gas. Local anesthesia is disadvantageous because of the danger of opening lymph channels for metastatic invasion. Block anesthesia is very good, but it is not

tion, depend upon subsequent irradiation to control it.

Our needles are threaded with fine non-corrosive wire, this in preference to silk thread, which is uncertain because it breaks

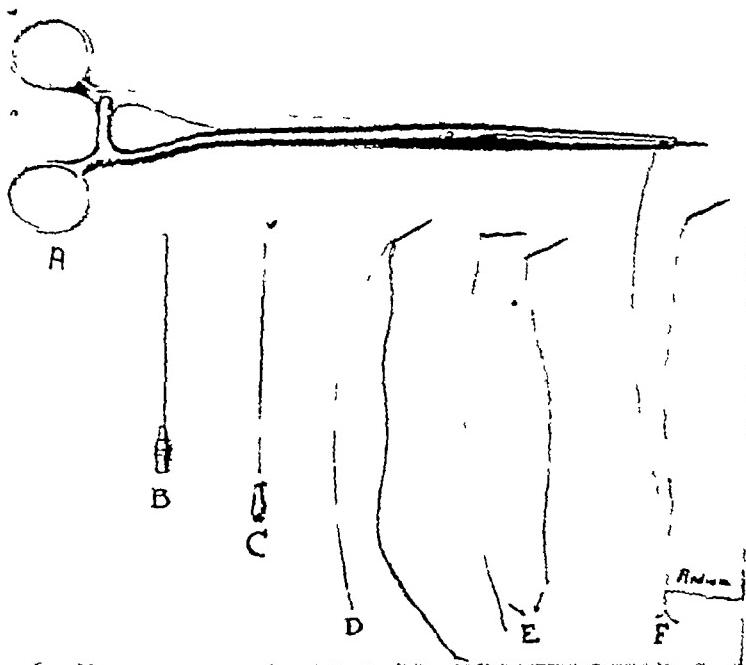

Fig 2. (A) Needle holder, with needle in position for implantation, (B) Cannula, (C) Trocar—note the flat sides which permit egress of the wires, (D) Needle threaded with black silk and wire, (E) Two needles threaded with wire, (F) Needle threaded with white silk for superficial work.

applicable to all locations. The skin is prepared as for a major operation and all aseptic precautions are observed. A bistoury is used to incise the skin, and through this small incision the needle, held in a needle holder as a spearhead on a spear, is plunged directly into the carcinomatous mass. Trocar and cannula are used in very deep lesions in which one must traverse normal areolar tissue (Fig 2).

We attempt to reach the palpable border of the neoplasm, embedding one-half the needle length in the neoplasm. This serves to hold the needle firmly and catches outlying groups of carcinoma cells. We are not unmindful of Handley's microscopic growing edge, but, in view of its uncertain loca-

too easily and in most embarrassing situations. In intra-oral work the needles are threaded with wire and black silk. With the silk they are sewn *in situ*. In treating large lesions in which more than five needles are necessary, the implantation is done in two stages, re-implanting upon removal.

Each of the needles contains 10 mg and is permitted to remain *in situ* ten hours, i.e., 100 mg -el hours.

DANGERS AND EXCEPTIONS

Needle implantation is never undertaken through an ulcerated or infected surface. Intra-oral work requires chemical sterilization of the field before insertion. Infection carried into the depths of an actively

growing carcinoma is certain to lead to increased rapidity of growth

Displacement of a needle after insertion is a serious matter, as proximity to the skin for the full time will cause a severe burn

prevent this misfortune. Occasionally in implanting radium needles a sensory nerve lies along the course of the needle and receives maximum radiation. This causes most excruciating pain of months' duration, for

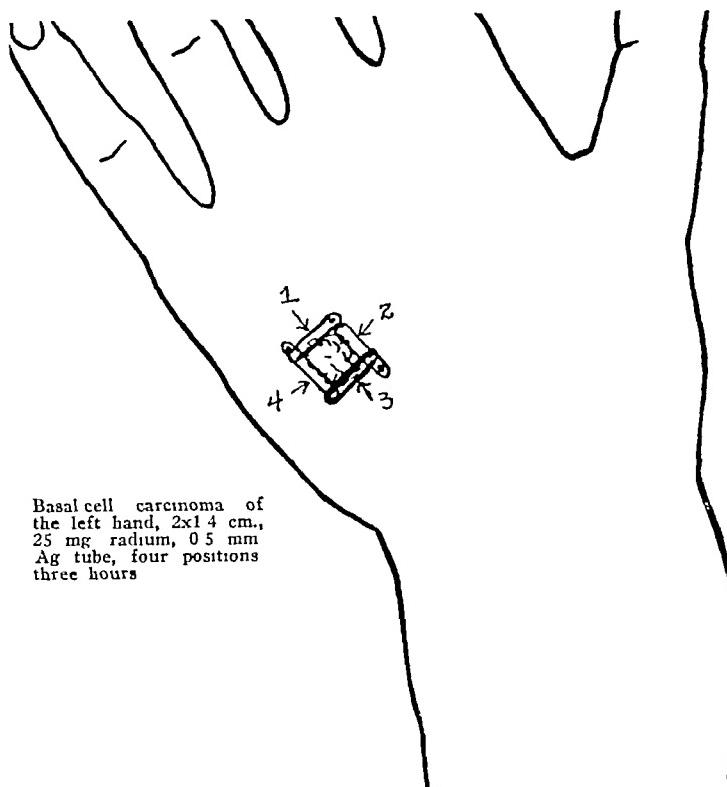

Fig 3 Superficial carcinoma of the hand, mapped after biopsy

As a precautionary measure the wires projecting through the puncture wounds are fastened with adhesive plaster, sterilized in a lamp, at their point of exit through the skin. Dressings and bandages are applied over this. Care must be exercised in implanting if nodules are subcutaneous—the time must be reduced or the needle implanted deeply so that the lesion lies between the needle and the skin.

Fatty tissue and bone must not be heavily irradiated if avoidable. There is danger of fat necrosis and bone devitalization (5), both of which are unpardonable sins. Only painstaking care and good judgment will

afford relief.

Tonsillar lesions require 80 mg -el -hrs as the lymphoid tissues are usually radiosensitive and there is danger of sloughing and hemorrhage. The grading of the dose is a matter of judgment which depends on the type of growth and its comparative radiosensitivity. Only a few reports are available which are of scientific value, notably Quimby and Martin's (6). Modern therapy demands this type of work.

Although we are using steel filtration, we contemplate changing to platinum, 0.5 mm wall thickness. The increased filtration re-

SURFACE RADIATION

After having observed bare tubes, gold tubes, and steel needles generously implanted in carcinomas, we are convinced that the indications for interstitial radiation are daily becoming more circumscribed. We feel that operative interference with inoperable carcinoma opens avenues of infection, lowers the resistance of the host, and damages local resistance. Attention need only

surgeon attempts a block dissection of the neck but on exposure finds that nodes apparently free-lying before operation are hopelessly embedded, making resection impossible.

Our experience has been that although these patients get primary skin union the neoplasm takes on added malignancy and the termination is hastened, in spite of the fact that only the skin and superficial fascia have been disturbed. In such extensive dis-

ease external radiation offers the best chance for control Interstitial radiation would require multitudinous emanation implants evenly distributed A trial of this method suffices to convince one that the homogeneous distribution of radiation in three planes is indeed theoretic

Surface radiation has great possibilities, more especially so since the introduction of high filtration Forssell (7) classifies lesions of the skin as superficial and infiltrating This is applicable and may be carried with advantage to other locations Further clarity may be secured by subdividing these two as follows

(A) Superficial
 Ulcerating
 Non-ulcerating

(B) Infiltrating
 Ulcerating
 Non-ulcerating

Superficial Non-ulcerating Lesions—These are best treated with a filtration of 0.5 mm Ag and 1 mm of rubber We do not wish to produce ulceration by our treatment, therefore we encase our 25 mg silver capsule in rubber tubing—wall thickness, 2 mm—which serves to remove the secondary radiation of the silver Silver, 0.5 mm, removes 25 per cent of the beta radiation, the remaining 75 per cent and the gamma rays being effective The erythema time is 50 mg -el -hours

The silver tube is applied to skin lesions with adhesive plaster The lesion is measured, mapped, and photographed, and a time plan of radiation made (Fig 3)

Superficial Ulcerated Lesions—These are treated with the naked silver tube, and, as before, it is applied on adhesive plaster or a moulage, after mapping This radiation is the most caustic used in treatment

Although the erythema time is 35 mg -el -hrs, we routinely give 75 mg -el-hours Quimby's erythema (8) is a faint blush on the skin of 80 per cent of a group of normal

individuals after fourteen days In treating carcinoma, we are not satisfied with "faint blushes"—we desire maximum effects compatible with reparative processes, *i.e.*, the epidermicidal dose We omit the rubber because the ulcerating carcinomatous surface affords this filtration for the deeper structures which we wish to treat, and aids by destroying superficial cells by caustic lysis

Dangers—The application of radium in this form adjacent to cartilage, *i.e.*, the ear, will give rise to a perichondritis This is painful, very difficult to heal, and always to be avoided In locations in which cartilage is subjacent, surgical diathermy offers the superior method of treatment

Because repeated small doses have a tendency to produce a chronic ulcer with a fibrous base, it is important to avoid them This is evidence of inadequate primary treatment, and the resulting type of ulcer is malignant, non-healing, and unresponsive to any type of therapy Electrocoagulation offers the best chance for cure Surgical intervention results almost invariably in a severe cellulitis or erysipelas The malignant cells seem to be enmeshed in a fibrous matrix, the growth impulse held in abeyance, insufficient nourishment reaches the surface so that infection cannot be coped with nor healing occur A disturbance of this symbiotic community leads to rebellion and the rapid increase of one or the other element, failure to attack the lesion leads to slow but sure malignant progress

Infiltrating Ulcerated Lesions—With the quantity of radium at our disposal we can prepare a 50 mg capsule, wall thickness 1 mm or 2 mm, and a 25 mg capsule with the same wall thicknesses Higher filtrations can be obtained by having lead capsules made We are using 3 mm of Pb

Capsules are used primarily in the infiltrating lesions, being encased in 2 mm rubber tubing when they are used in contact Experience alone can aid one in a decision

as to when to apply capsules in contact and at a distance. In general, however, in lesions of the mouth or in body cavities, they must perforce be used in contact, whereas in surface lesions space is available for distance therapy.

Various applicators are available for intra-oral work, of which the lead spoon, the center-board holder, and the tonsil clamp are the best known (Fig. 4).

With 1 mm brass, 2 mm rubber filtration, the erythema time is 64 mg -el -hours. Practically, we give 100 mg -el -hrs plus. This dosage can be repeated every other day until 400 to 600 mg -el -hrs are given. The reaction is very severe, requiring six weeks for healing. With these intra-oral applicators, fixation cannot be rigid, so that the area treated is not accurately computable, this accounts in a large measure for the huge dosage one may give with comparative safety.

Lesions situated about the eye necessitate protection of the eyeball. Lead plates 2 mm thick are cut to fit the conjunctival sac, hammered until they fit the curvature of the eyeball, smoothed, and polished until they are flawless. After cocainizing the eye these are slipped into the conjunctival sac before the treatment is started.

RADIUM IN THE CERVIX UTERI (CARCINOMA)

The naked 1 mm brass capsule containing 50 mg is used with a semi-flexible brass wire through its eye. This is inserted in the external os after biopsy and chemical sterilization of the surface. The vagina is packed tightly. The knee-chest posture aids greatly and an intra-vaginal light is indispensable. The dose is 50 mg given for 16 hours, a total of 800 mg -el -hours.

After 48 hours, a second application is made and, if the canal is patent, the 25 mg capsule in brass precedes the large capsule in an attempt to reach the fundus. The

50 mg capsule is placed in a midcervical position. Again 16 hours is given. A third similar treatment is given after the 48-hour interval, the total intracervical dosage being 2,400 mg -el -hours. If the 25 mg capsule will enter the fundus, an additional 800 mg -el -hrs may be added to this.

Vaginal applications follow at 48-hour intervals. A cork 2.5 cm in diameter is bored to take a 50 mg lead capsule of 3 mm. wall thickness. This is used in the three positions—right, left, and across, or the H series. The erythema time is 800 mg -el -hours.

This is the technic advocated by Bowing (3) with modifications and is excellent for those who possess only small quantities of radium.

Infiltrating Non-ulcerating Lesions.—These are treated by radium packs and moulanges. The greatest distance compatible with duration of treatment and efficiency is 3 centimeters. There are those who would use the convenient and better distance of 4 mm, but with only 75 mg of the element the time is too long. For the sake of convenience, we use distances of 1 cm, 2 cm, and 2.5 cm, or one inch. All areas are blocked out in carboltuchsin or ink in 2.5 cm squares. All corks for treatment are cut 2.5 cm square.

The erythema time at 1 cm with 1 mm brass filter, 2.5 X 2.5 cm area, is 294 mg -el -hours. We give 600 to 800 mg -el -hrs in one week.

Upon increasing the distance to 2 cm, we increase the time to 350 mg -el -hrs, whereas at 2.5 cm, 500 mg -el -hrs can be given.

Moulanges may be made of Columbia paste or dental compound. Regaud believes Columbia paste produces secondary radiation which is advantageous. Columbia paste can be made in any laboratory, is inexpensive, and is very easily handled. For irregular or inaccessible lesions this is an ideal

Fig 5 Parotid tumor before radiation

Fig 6 Lesion mapped for radium therapy

Fig 7 Radiation response. Erythema three weeks after the last radium application

method of treatment. At the Radium Institute in Paris the smaller moultages are saved, and the location of the radium tubes indicated by thick wire. Should the patient develop a recurrence, its location is compared with the moulage so that the defect in treatment may be corrected in subsequent cases. The paste is warmed in hot water until soft, gently applied to the surface or lesion. Cold water is used immediately upon its removal to chill it so that it retains the shape of the lesion. Distance can be secured by planting the tubes on the exterior of the moulage in grooves made by a hot wire.

COMBINED RADIUM AND X-RADIATION

The use of two types of radiation over the same skin area is not new, but is productive of excellent results and deserves wider use than it now enjoys. Rather than go into an elaborate discussion of theory and methods we will report the treatment as actually given in a case of parotid tumor.

The parotid tumor, which measured 4 cm in diameter, was raised 2.5 cm from the normal facial contour (Fig 5), covered with distended venules, slightly reddened, hot to the touch, and firmly fixed to the deep structures, but not to the skin. There was no lymphadenopathy, and the routine laboratory examinations were negative.

The X-ray treatment was given first—eight treatments in a period of sixteen days—rising by 30 per cent doses to 90 per cent, maintaining this figure plus or minus 5 per cent for the period. The total radiation was 335 mma, 140 K V, 5 ma, 4 mm Al filter, at a skin-target distance of 40 centimeters. The area covered the cheek, adjacent neck, and ear.

With the before-mentioned factors the erythema time was 175 mma—the machine has been calibrated by J. L. Weatherwax. The 335 mma dose is 191 per cent of an erythema dose.

A fortnight later, radium therapy was instituted. At this time a small sinus had opened in the center of the tumor mass, but no pus or secretion discharged. It presented the typical appearance of malignant ulceration with rolled edges.

Ten areas (Fig 6), each measuring 2.5 sq cm, were laid out over the neoplastic area. A square cork, 2.5 cm on each side, was cut 1 cm thick and to the superficial side of this the two brass capsules of 50 and 25 mg, respectively, were strapped. Wall thickness 1 mm brass. Each area was numbered and treated in rotation for three hours, i.e., 225 mg-el-hours.

On the eighteenth day after the radium treatment, the patient had a severe erythema with desquamation, but no blistering. The sinus was closing and the pain relieved (Fig 8). On the thirty-second day the erythema had diminished, evidencing a tendency to browning and early desquamation. The center of the tumor was shrunken and sclerotic, the periphery was a hard fibrous mass one-third the previous size.

Quimby (8) reports on the theoretic aspect of combined radiation, Widmann on the clinical application of two types of radiation. It is beyond the scope of this paper to discuss the theory—suffice to say the results are far superior to one type of radiation in selected cases.

SUMMARY

Small quantities of radium may be used to great advantage by an experienced, well-trained, and ingenious radiologist.

A detailed review of methods now in use in this laboratory is given, omitting statistics and striving for simplicity and clarity.

The apparent simplicity of these methods should not becloud the fact that a great deal of wisdom, tact, and experience are necessary in their use, and that the tyro will fail if he attempts it.

TWO UNUSUAL CASES REVEALED IN ROUTINE ROENTGENOGRAPHY¹

By C. C OWEN, M.D., SAN BERNARDINO, CALIFORNIA

OCCASIONALLY in the smaller communities an odd case is accidentally disclosed during the process of a roentgen examination

In the cases considered at this time, the first is a regular routine examination of the nasal accessory sinuses in a boy, nine years of age, which showed, in addition to the sinus and nasal pathology, a striking fold of increased density intracranially in the left parietal area. The second was an X-ray examination for a suspected fracture of the left clavicle in an infant, nine months of age, which showed no evidence of a fracture, but a suspicious shadow in the left thorax resembling the gastric saccule, without a definite shadow of the cupola of the left diaphragm.

Case 1 H A., aged 9 years Height, 4 feet 2 inches Weight, 66 pounds Pulse, 80 Temperature, 98.6 Blood pressure 114/76 The boy, of well nourished and healthy appearance, was of the phlegmatic type. His father, whose health previously had been good, had died at 26 years of age of sinus thrombosis following an infected third molar. The mother, aged 32 years, was living and well.

Personal History—Malnutrition in infancy, scarlet fever, whooping cough, mumps, chicken pox, pneumonia. There was no syphilitic history and the Wassermann test was negative.

There was no history of injury at birth. During infancy there was a period of malnutrition at six months, with some convulsive attacks. At that time there was a noticeable increase in the size of the cranium, but no definite history of a true hydrocephalus or meningitis is obtainable. There is an indefinite history of a scalp laceration in the frontal region at six years caused by a falling object. The boy's health had been apparently good, with the exception of the usual diseases of childhood, as enumerated above, until two years previous to examination, when the headaches began. They were accompanied by a sense of pressure in the left parietal region and frequent attacks of epistaxis. The mother noticed a seeming retardation of the mental development also.

Roentgen Findings—On Aug 25, 1930, the first roentgen examination was made, following complaint of nasal accessory sinus pathology causing chronic headaches, epistaxis and occluded nasal passage on the left side, and lethargy. The films of the first examination are not available, but at that time there was a definite increase in density involving the right antrum, marked deviation of the nasal septum to the left, with occlusion of the left nasal passage and poorly defined anterior ethmoid cells. In addition, there was a striking fold of increased density apparent in the left parietal area, intracranially, which was obviously abnormal and stimulated interest on account of the headaches and sense of pressure in this region.

A second roentgen examination was made Sept 9, 1930. The same sinus and nasal pathology was demonstrable, and in the different views of the skull the increased density noted was more apparent and better demonstrated. There was a definite increase in the size of the calvarium in relation to the face and mandible. In the postero-anterior view, taken at 107 degrees, the widest horizontal diameter was 19.7 centimeters. The fold of increased density on the inner

¹Read before the Radiological Society of North America at the Sixteenth Annual Meeting at Los Angeles, Dec 1-5 1930

Figs 1 and 2 Postero-anterior views of the skull in Case 1, showing increase in the size of the calvarium and fold of increased density on the inner surface of the cranium (See text.)

surface of the cranium in the left parietal area extended from 2 cm left of the sagittal suture to the left mastoid area, being about 13 cm at the thickest part. The tables showed no definite bony production or destruction and the fold was not of the density of calcium, it was apparently a soft-tissue shadow. The antero-posterior view of the occipital area showed this density more distinctly, and here it measured 18 cm at the thickest part. The lambdoidal sutures and the inner table of the skull were well defined and apparently intact in this view. The fold was accentuated by a channel of decreased density which seemed to communicate with the middle meningeal groove, especially in the postero-anterior views, in which the longitudinal sinus was visible and apparently dilated.

In the left lateral view of the skull, the occipito-frontal diameter was 20.1 centimeters. The inner table was well defined and there was a triangular area of increased density at the vertex, just posterior to the bregma, with the base at the groove for the middle meningeal vessels and the apex touching the inner table in the left parietal area about 5 cm posteriorly. It was 2 cm wide at the base. The groove for the middle meningeal vessels was very definite and apparently widened, at least more so than usual, and it seemed to invade the inner table at the vertex. This increased density and the wide meningeal groove were not apparent in the right lateral view of the skull. (This film, as well as the films of the first examination, was lost when the case was referred.)

These findings show definite evidence of a pathologic lesion intracranially, suggestive of a thickened fold of dura mater coincident with a probable aneurysm involving the middle meningeal vessels, and dilatation of the longitudinal sinus demonstrable at this examination.

Operative Findings—This case was referred to Dr Cecil Reynolds, of Hollywood, for diagnosis and treatment. After finding neurologic evidence of intracranial pressure in the area noted, the pre-operative diagnosis was an old, organized, extra-dural hemorrhage. The operation consisted of the fashioning and turning downward of a left parietal osteoplastic flap. Very severe bleeding from a large vessel passing to the bone from a dilated lacunal varix was encountered, also from a slight tear in the large ascending abnormal dural vein, running directly up to the varix. Muscle grafts were placed on each of these bleeding points as the brain pressure, which was at first markedly excessive, gradually diminished. Cotton pads had to be placed over the grafts to hold them *in situ*, and the flap temporarily replaced with silkworm-gut. The enlarged dural vein was tied in two places below the varix.

Post-operative Diagnosis—Diagnosis was of a varix connected with the longitudinal sinus, secondary to an internal hydrocephalus. The following day the flap was turned downwards, the cotton pads soaked off with saline, and the grafts pressed on firmly. The flap was replaced, after all the blood was cleansed, with two cigarette drains (Penrose) projecting through each drill hole to drain the surface of the dura. The dura was never opened. The thickened dura was thought to be the result of an early inflammation of the meninges.

Differential Diagnosis—The lesions most commonly found affecting the external surface of the brain are the arterio-venous and venous malformations, as stated by Cushing.

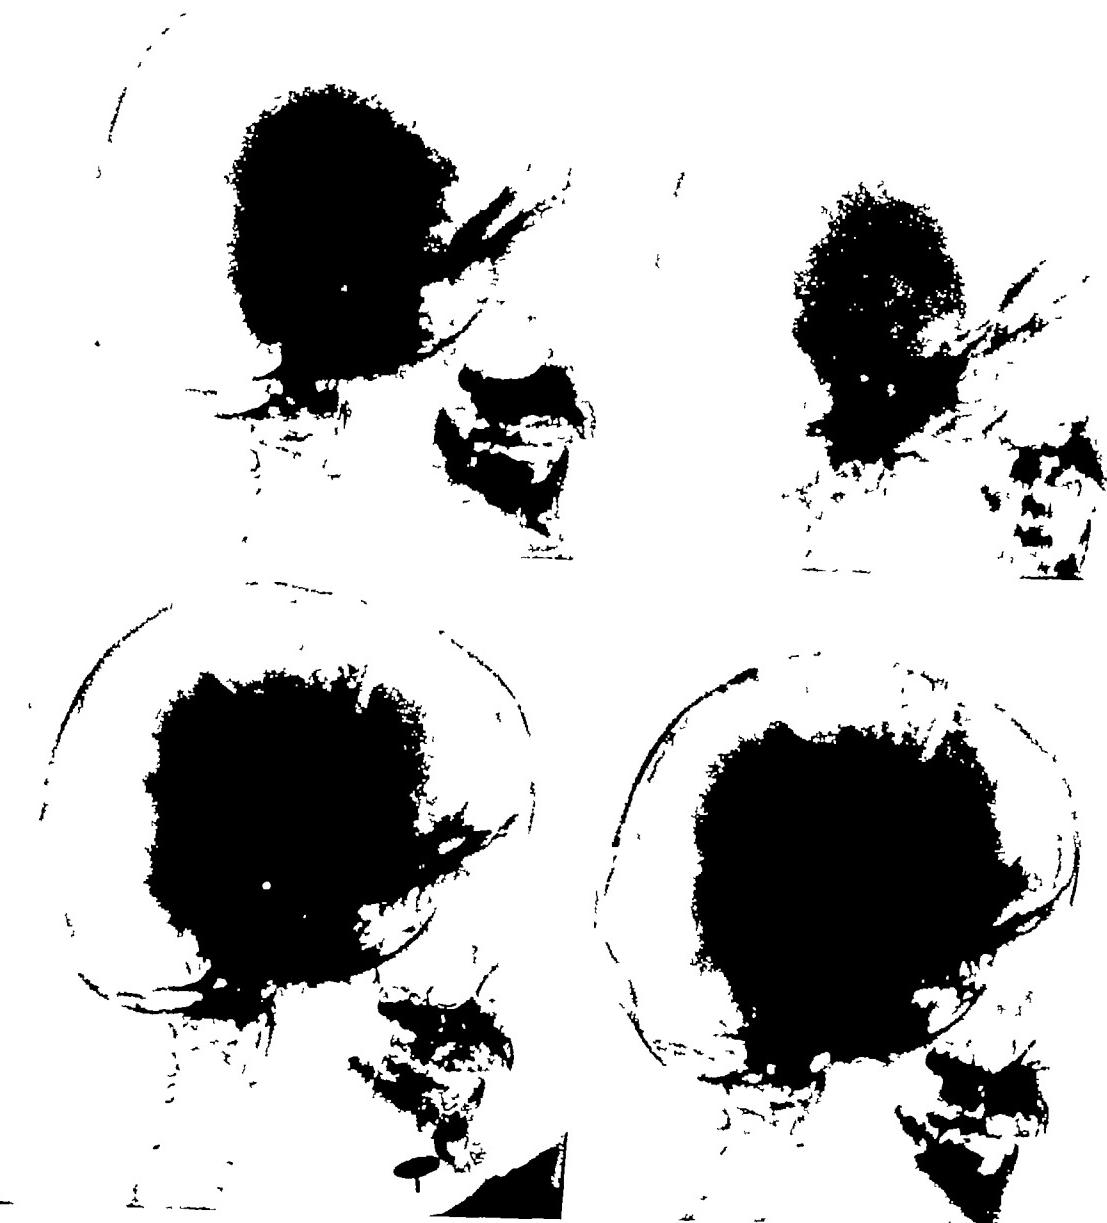

Fig 3 Case 1 The dense fold here measures 18 cm at its thickest part

and Bailey, which are primarily surface lesions of the hemispheres. Types may be recognized as simple enlargement of a single vessel, one or more vessels, or complicated racemose types. The lesion extends from the cerebral surface, like an inverted cone with the apex abutting a ventricle, into which a terminal hemorrhage sometimes occurs (3).

Meningiomas or endotheliomas, formerly believed to originate from the dural surface, are now believed to originate from the arachnoid and to comprise about 12 per cent of intracranial tumors. There is usually irregular bone proliferation from the lesion extending and squeezing into the crevices and bone spaces, irritating the bone. Erosion, vascularity, bone changes, spicule formation, diffuse thickening, enlargement of the meningeal channels, and calcification are the results of these lesions (20).

Syphilis with headache, the commonest symptom, usually shows marked osteoperiostitis, circumscribed, multiple, or single, in

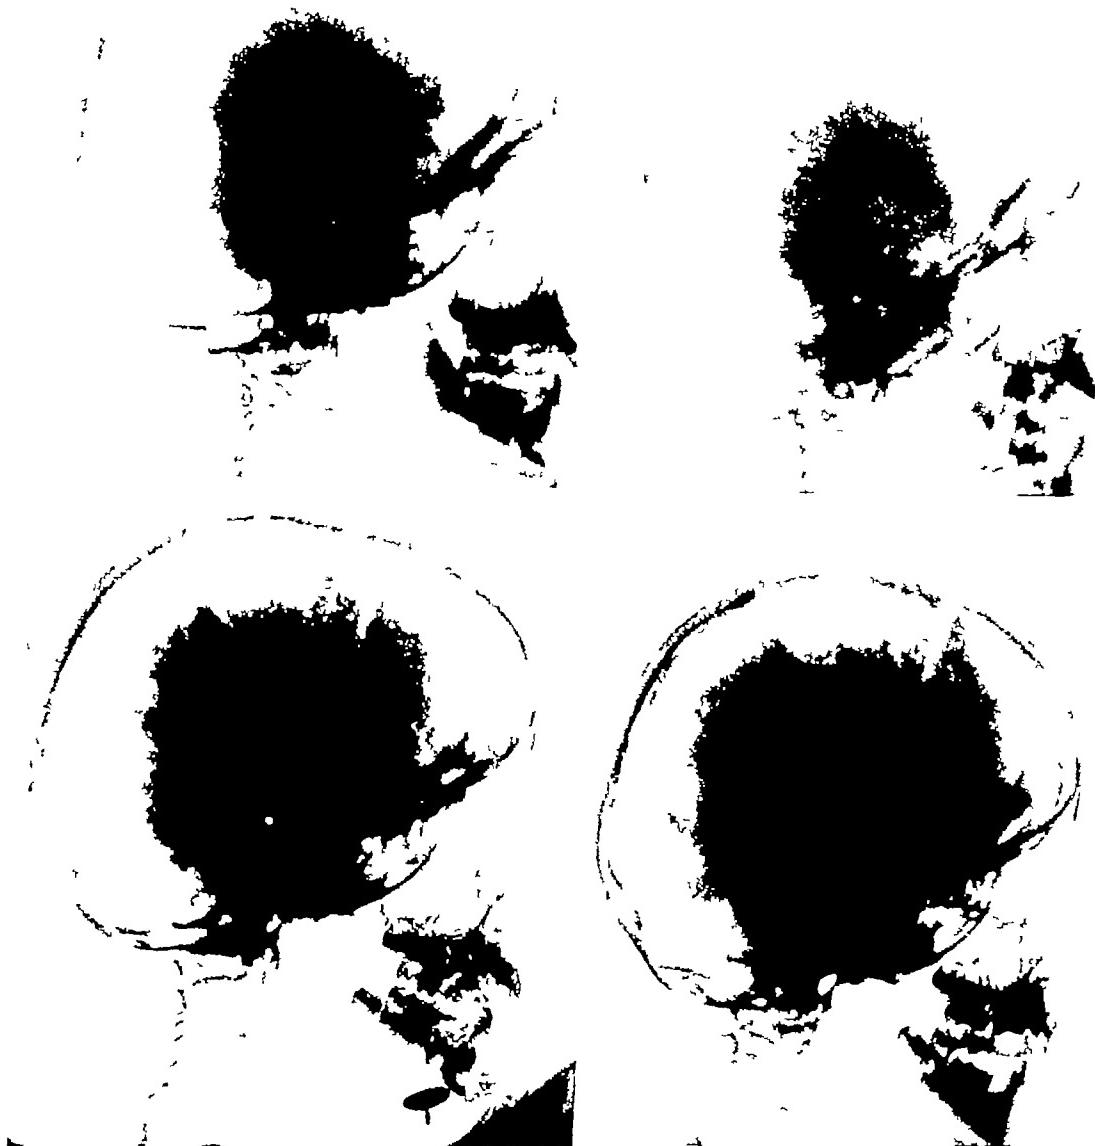

Figs 4, 5, 6, and 7 Lateral views of the skull in Case 1, showing the area of increased density at the vertex and the groove for the middle meningeal vessels definitely widened (See text.)

the cranial dome. The transparencies of gummas are usually round or oval.

Tumors of the soft tissues of the skull—angiomas, fibromas, dermoid cysts, and lipomas—may produce deformities of the skull, but they rarely produce new bone. They usually cause bone atrophy from pressure,

while malignant growths may infiltrate the bone or cause pressure atrophy.

Injuries of the skull and its contents form hematomas and aneurysms due to arterial injury, and cause atrophy from pressure. Concussions, contusions, or laceration of the brain, membranes, or vessels from

Figs 10 and 11 Postero-anterior views in Case 2, showing elevation and fixation of left diaphragm with resultant high position of the stomach and splenic flexure.

Case 2 F S., an infant aged nine months, was well nourished and normal in appearance. He was examined Sept 28, 1930, for a suspected fracture of the left clavicle following a fall from a high chair two days previously. The parents had noticed a limitation of movement of the left shoulder, and the child cried when it was moved. There was no definite evidence of a fracture demonstrable, but there was a

suspicious shadow in the left thorax resembling the gastric saccule, the splenic flexure was high, and the dome of the left diaphragm was not easily demonstrable. The heart, mediastinum, and left lung were displaced considerably toward the right. Physical examination showed some dullness in the left thorax, and there was a depression in the left costochondral margin which was apparently congenital. The apex beat was in the midline. There was no history of trauma except the recent fall from a chair. There had been gastro-intestinal symptoms of colic, and feeding difficulties, with regurgitation at times, which had been corrected by proper feeding formulae.

The following day, the child was immobilized by being wrapped in a sheet, one ounce of barium sulphate was added to the regular bottle feeding at ten o'clock, and administered under fluoroscopic observation.

Roentgen Findings—The barium mixture filled the esophagus, which descended as a straight column normally, slightly to the right of the vertebral shadow, to a point opposite the eleventh dorsal vertebra, where it entered the stomach. The fundus was apparently at the level of the third rib anteriorly on the left side, above this there was an unbroken curved arch of increased density identified as the diaphragm. It was

filled with gas and high in the thorax. The dome of the left diaphragm remained elevated in the thorax. There was a small resi-

due of barium in the descending colon near the sigmoid with the remainder in the distal colon and rectum

Differential Diagnosis.—According to Le Wald (11), certain congenital and acquired conditions of the diaphragm are classified as follows

- (1) Absence of left half of diaphragm
- (2) Thoracic stomach
- (3) Eventration of the diaphragm
- (4) Congenital hernia
- (5) Acquired hernia

(1) Absence of the left half of the diaphragm can be diagnosed by roentgen examination and roentgenograms, especially in the lateral view. A correct diagnosis of this condition is important, particularly in regard to the risk of surgical intervention, which is contra-indicated if the diaphragm is absent. A lateral view reveals the absence of a regularly curved or arched line of the diaphragmatic dome, which if present can be traced to its attachments.

(2) Thoracic stomach can be demonstrated by the roentgen examination and shows the stomach in the thorax with the diaphragm perfect in form below it and intact on both sides. No surgical intervention is necessary unless some gastro-intestinal complication occurs.

(3) Eventration of the diaphragm may occur on either side, but is usually on the left side. It may assume a high level and should always show an even curved outline, especially in the lateral view. Contrast opaque mixture is often necessary to differentiate the upper border of the stomach from the leaf of the diaphragm. It is usually due to atrophy of the musculature or secondary to phrenic nerve disease, and is sometimes very difficult to differentiate from diaphragmatic hernia with a sac, even with barium mixture or pneumoperitoneum—especially if the muscle fibers are exceedingly thinned out, or the sac presents an uneven curved line. However, a sac usually

shows a broken line and some angulation True eventration is irreparable and permanent (6)

(4) A defect in the diaphragm at birth (congenital hernia) may allow the abdominal contents to escape into the thorax on either side Identification of the diaphragm shadow is important, as hernia is operable

(5) Acquired hernia may result if the esophageal orifice is weakened or relaxed, with an escape of a portion of the stomach through it Identification of the hernia with barium and a distinct outline of the diaphragm are necessary, as this is an operable condition

Voluminous literature has arisen on the differentiation between eventration or elevated position of the diaphragm and diaphragmatic hernia, because the difference is often difficult to determine Both are departures from the physiologic, and are considered by some authorities to be different phases of the same trouble (8) A constant roentgen finding rather indicates eventration, while a variable condition suggests hernia Eventration is regarded etiologically as congenital and is irreparable There is also a difference in opinion regarding the movements of the elevated diaphragm Holmes and Ruggles (6) state that the movements are limited although normal, while in hernia the outline is obscured and the movements paradoxical Paralysis of the phrenic nerve also presents paradoxical movements Moore (14) says that the movements are reversed and that true eventration is rare, although since the use of the X-ray more cases are being discovered

Ritvo (15) states that congenital weakness of the musculature of the diaphragm is the probable determining factor in hernia, while eventration shows an elevation of the diaphragm with resultant high stomach, splenic flexure, and small intestine

Barium shows the esophagus rarely tortuous, which disappears with reduction It is usually angulated at the orifice

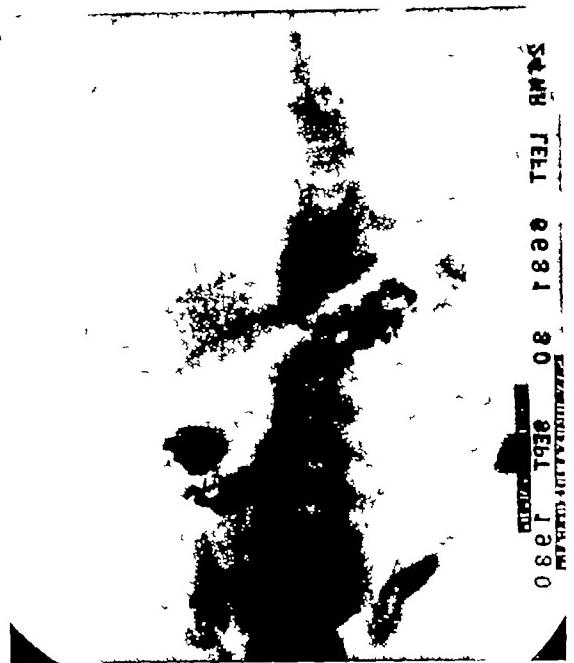

Fig 16 Postero-anterior view, after 24 hours, Case 2

Rusconi (16) denies the paradoxical movements or that pneumoperitoneum has any diagnostic value, and that eventration and hernia may have identical pathologic, anatomic, and clinical manifestations if the hernial ring is large The arched line may be the sac in true hernia, in false hernia and congenital absence the herniated viscous and lower boundary of the lung, and in eventration the relaxed atrophied diaphragm If the hernia is limited and the sac visible, the diagnosis may be made

Elevation due to pressure from below or traction above is usually temporary and not true eventration, according to Stoloff (19), who says that, notwithstanding the X-ray, eventration and diaphragmatic hernia remain uncommon, but that a smooth rounded dome, sharply defined—since the continuity is not disturbed—is probably eventration and not hernia Pneumoperitoneum will outline the leaf inferiorly, but with hernia the gas rises to the upper limit of the herniating mass, indicating absence or limit of the diaphragm, while an angulation above

the mass suggests herma. All the facts must be available, and even then a differentiation is sometimes impossible, according to Schonfeld (17), and errors are easily made (14).

Conclusion—In this case the esophagus was apparently straight and not tortuous or shortened, while there was an apparent congenital anomaly of the stomach and duodenum, with elevation and fixation of the left diaphragm and resultant high position of the stomach and splenic flexure in the thorax. The heart, mediastinum, and left lung were displaced toward the right side, and there was an unbroken distinct arched line of the elevated diaphragm demonstrable in both postero-anterior and lateral roentgenograms when the contrast mixture filled the stomach. These findings, in the absence of a history of definite early trauma or clinical symptoms, rather indicate the condition to be one of true congenital eventration of the diaphragm, and an anomaly of the stomach, not amenable to operation unless some complication arises.

HEPATOSPLENOGRAPHY

ROENTGENOLOGIC DEMONSTRATION OF THE PARENCHYMA OF THE SPLEEN AND LIVER BY
MEANS OF A NEW INTRAVENOUS CONTRAST MEDIUM (THOROTRAST)

By DR SILVIJE KADRINKA, First Assistant in the Central Institute of Radiology in the
Canton Hospital, Dr R Gilbert, Director, GENEVA, SWITZERLAND

Translated by H C OCHSNER, M D, INDIANAPOLIS, INDIANA

IT IS a great privilege to report herewith a new method by which the liver and spleen are made roentgenologically visible following intravenous administration of a colloidal contrast medium. The results obtained in a series of cases in which this method was used will be described.

The possibility of direct visualization of the liver shadow was suggested by the visualization of the gall bladder obtained by Einhorn (1), following administration of tetraiodophenolphthalein, and the use of toradol later suggested for hepatosplenography by Oka (2) and Radt (3). This new colloidal contrast medium is not precipitated by the organic fluids and has been used for retrograde pyelography. After experiments on animals controlled by anatomic studies made by Dr J Rossier (4) in the Pathologic Institute of Prof M Askanazy, a clinically applicable method was developed which makes possible the roentgen visualization of the liver and spleen without risk to the pa-

tient. The author (5) has used this method on patients in Prof M Roch's University Clinic for Internal Medicine.

Thorotrust is a 25 per cent thorium dioxide sol containing 22 per cent of metallic thorium. It has a bluish, milky, shimmering appearance in reflected light. In transmitted light it appears as a clear, brownish fluid. For intravenous use it is diluted at least ten times with 5 per cent glucose solution, sterilized by heating, and injected in increasing doses in the course of several days. To determine the patient's tolerance, an initial dose of not more than 0.1 gr of thorotrust per kilogram of body weight is given. After that, each dose is increased from 0.1 to 0.05 gr per kilogram of body weight until the desired dose is given, care being taken not to exceed the patient's tolerance. As a rule, a total of 0.8 gr of thorotrust per kilogram of body weight is enough to produce an intense shadow on the roentgen film, the density of the

Fig 1 Hepatosplenogram of a normal liver and somewhat hyperemic enlarged spleen. (Rays directed vertically, patient lying on abdomen.)

Fig 2 The same case radiograph of the abdomen before injection

Fig 3 Hepatosplenogram of an ectopic, vertically elongated liver and a normal spleen (Margins indefinite due to movement, patient in stupor)

Fig 4 The same case with patient on her back. Due to abnormal mobility, the liver has assumed a horizontal position under the diaphragm

liver being approximately equal to that of the vertebrae, and the density of the spleen to that of the ribs (Figs 1 and 2). In

the event that visualization of the margins of the liver and spleen is all that is desired, one-half to one-third of the dose is sufficient.

Roentgen observation should be made 24 hours after the last injection, and a flat dorsoventral plate of the upper abdomen, taken with the patient in the supine position, is ordinarily sufficient. If the organs are abnormal in structure or position, special views are necessary, using a definite technic (6). The patient lies on the abdomen and the rays are directed dorsoventrally at an angle of from 20 to 30 degrees toward the patient's head, so that the liver is visualized in its greatest transverse and smallest vertical diameter. In the event that there is an appreciable variation from the normal position, the direction of the rays is correspondingly changed so as to be perpendicular to the plane of greatest diameter of the liver.

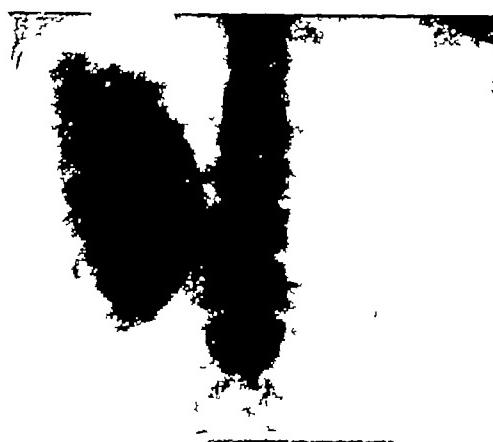

Fig 5 Hepatosplenogram in a large chronic permanent splenomegaly. There is absence of the spleen shadow. The somewhat enlarged dense liver shadow is displaced to the right and downward (dorsoventral view).

Fig 6 The same case hepatogram in oblique position

Fig 7 The same case before injection. The greatly enlarged spleen displaced downward, the barium-filled stomach and small bowel (Patient standing)

The technic of Rieder and Groedel is applicable to the spleen.

The intense shadows of the liver and spleen are due to the storage of the electrically negative colloidal particles of thorium in the reticulum cells in the pulp of the spleen and in the Kupffer cells of the liver (of which from four to five containing granules are visualized in every microscopic field of histologic specimens). Some of the colloidal particles are also demonstrable in the bone marrow, lungs, and adrenals, but the resultant increase in density is insufficient to render them visible in the roentgenogram. After a limited time interval, no anatomic changes could be demonstrated in the tissues of experimental animals.

The injections are generally well borne, and, aside from occasional transient dis-

turbances, no serious complications have occurred. In three cases there was vomiting, twice in patients with cirrhosis of the liver and once in a case of chronic nephritis. In a patient with a large chronic splenomegaly of unknown nature, there was a slight hemolytic shock following the last injection, which was readily relieved by an injection of adrenalin. A fit of coughing was produced in an asthmatic patient.

The hemoglobinuria occasionally observed in guinea pigs has not once been observed in 25 injections in humans and was evidently due to faulty technic in the experimental animals. Blood studies showed a slight, transient diminution in the erythrocyte count. Liver function and other clinical examinations were entirely negative. Although the method gives precise information about

the topography of the liver, it is particularly indicated in those diseases of the liver or spleen in which circumscribed pathologic-anatomic changes take place. In cases in which the normal tissue is displaced by a

shadow was obtained in a case of cirrhosis (8) in which the spleen was enlarged and cast a good shadow. The enlarged spleen was poorly visualized in a patient who had malaria (therapeutic), and there was a com-

Fig. 8 (left) Radiograph of the liver of an experimental animal injected with very large doses of thorotrust

Fig. 9 (right) Radiograph of the spleen of an experimental animal impregnated with a large dose of thorotrust

tumor mass, an echinococcus cyst, a circumscribed abscess, a syphilitic gumma, etc., the contrast medium is not absorbed, and a negative shadow is visualized on the roentgenogram, as Radt (7) demonstrated in two cases of cancer of the liver. As the various processes differ in their pathologic-anatomic picture, so also different and characteristic shadows are obtained. Care must be taken not to confuse gas in the intestine for intrahepatic negative shadows.

Disease processes which produce diffuse pathologic-anatomic changes in the liver and spleen seldom constitute an indication for the examination. For example, a poor liver

plete absence of the spleen shadow in a very large permanent splenomegaly of unknown etiology.

The contra-indications are those pathologic conditions in which the colloidal contrast substance cannot be taken up by the reticulum cells and might produce injury due to its prolonged period of circulation in the blood stream.

After the rapid administration of very large amounts (15 to 20 times that ordinarily used) of thorotrust intravenously, the author found in guinea pigs that the reticulum cells of the liver and spleen were unable to absorb all the colloidal contrast

medium so that many granules were not only absorbed by the reticulo-endothelial cells of other organs but by the endothelial cells of the glomeruli of the kidneys.

There was hyaline degeneration of many glomeruli, and the liver cells assumed a necrotic appearance. The method should therefore not be used in patients with severe hepatic or splenic insufficiency, especially those in whom there is also some renal damage.

The picture in specific diseases of the reticulo-endothelial apparatus, for instance Gaucher's disease or lymphogranulomatosis, is still unknown, and it will be necessary to exercise great caution in their investigation.

Thorotrust, the suspensoid which is used, is not toxic. Like other thorium-containing colloidal contrast media, it is not attacked by acids or alkalies even in high concentration. Bluhbaum, Frick, and Kalkbrenner (9) injected thorium hydroxide sol subcutaneously in animals, and six months later were unable to demonstrate histologically any cell changes. The author's animal experiments similarly show that thorotrust produces no injurious effects unless it is given rapidly in large doses. With very large doses, the author and J. Rossier obtained osteomyelograms (Fig. 10) and nephrograms (Fig. 11).

Several months after injection of thorotrust, animals were found to be normal, two guinea pigs, one of which received massive doses, bore normally developed living young. Weight loss occurred only in animals which had received a much larger quantity of thorotrust than is necessary for hepatosplenography.

The excretion of thorotrust is very slow and the liver and spleen shadows produced by the contained thorium persist for a long time. Only after a period of several months is there an appreciable diminution of the shadow density. Probably a portion of the thorium is excreted through the lungs, since

Fig. 10 Experimental osteomyelogram in a guinea pig. Lateral view of the leg.

granules in appreciable numbers are always found in the endothelial cells of the pulmonary alveoli. The extent to which the liver and kidneys take part in the excretion is not entirely known.

The radio-activity of thorium is apparently too slight to produce any harmful effects in the comparatively short time it remains in the organism. In the Radium Institute of the Academy of Freiburg, umbrathor was investigated for its radio-activity. The thorium dioxide content of this substance is equal to that of thorotrust. One hundred cc of this colloidal sol contains a quantity of radio-active substance, the gamma-ray equivalent of which is that of the gamma rays of 1.24×10^{-6} gr of radium. Since only 40 gr of thorotrust

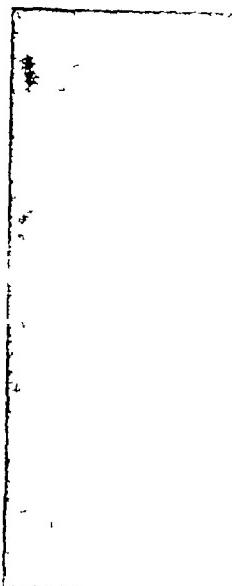

Fig 11 Experimental nephrogram in a guinea pig

are required to produce good visualization of the liver and spleen in a 50-kilogram individual, the total gamma-ray equivalent is that of the gamma rays of 0.496×10^{-6} gr of radium

Thorotrast is a preparation of non-toxic nature which, in contrast to umbrathor and tordiol, is unchanged by the action of the body fluids, as Weiser (10) has demonstrated. J. Rossier and the author have shown in animal experiments that it can be introduced into the blood stream without the production of capillary emboli. It should, therefore, achieve a sphere of usefulness not only in the limited field of medical roentgenology, but also in other branches of clinical medicine. It is more readily tolerated than the colloidal metals which have heretofore been used in medicine for non-specific therapy. Small doses could be used in the treatment of various acute or chronic diseases such as syphilis or tuberculosis.

Another phase that should be investigated is the sensitization of the cells to radiation therapy in the presence of tumors. The author noted a striking therapeutic effect in some of the patients he examined whose

reticulo-endothelial apparatus was apparently normal. Two patients whose condition before injection was so poor that they were regarded as hopelessly incurable were greatly improved in a relatively short time.

CONCLUSION

It may be said that the above described method of hepatosplenography has given entirely satisfactory results from the roentgenologic, clinical, and anatomic standpoints, and has appeared harmless over a limited time. In many instances it was apparently of therapeutic value. Until it has been used in a larger series of cases and these have been observed for a longer period of time, it should not be used routinely, especially in young individuals. The indications at present are limited to cases of carcinoma, echinococcus cysts, and abscess of the liver and spleen, especially those in which there is a likelihood of subsequent surgical interference.

New Super X-ray Tube Equal of World's Total Radium—All the radium in the world could not make more intense rays for the treatment of cancer than the new 900,000-volt, cascade X-ray tube of the New York Memorial Hospital, Dr G Failla recently told his fellow-physicists at the meeting of the American Physical Society.

One and one-half inches of lead are easily pierced by the rays from the new tube, which was developed by Dr W D Coolidge

Danger to workers with this tube, run for

several hours a day, is considerable, said Dr Failla, in describing the protective means employed in the laboratory

Running at 700,000 volts and five milliamperes, the radiation from the tube is equivalent to the rays from 600 grams of radium, the total amount isolated pure in the world. Some eight grams of this—more than anywhere else in the world—is located at the Memorial Hospital itself.

New methods of treating cancer victims were sought in these experiments, comparing the new X-rays with radium rays.

THE VIENNA RADIOLOGICAL SOCIETY

SESSION, MAY 5, 1931

Translation by HENRY RIGGS WOLCOTT, CHICAGO

Chairman, Professor Kienbock, *Secretary*, Dozent Fleischner Professor Kienbock and Professor Schwarz expressed their thanks for having been chosen as chairmen of the Society

THE TECHNIC OF IRRADIATION OF THE TONSILS

DR G SCHWARZ The subject of the technic of tonsillar irradiation has been brought again to the forefront of interest by several German publications containing comprehensive statistics Several hundred cases with good results in from 80 to 90 per cent are reported In 1911, Menzel, in addressing the Vienna Laryngologic Society, was the first to announce good results from roentgen irradiation in chronic tonsillitis Through improvements in the technic it has become possible, in recent years, to improve the method Going back to my last presentation of patients before the Gesellschaft der Aerzte, I wish to give some further details in regard to the technic A correct technic is very important Failures and good results tardily secured are due to unsuitable technic but are adduced to discountenance the method

First, as to the shielding of certain parts After various experiments, I have found that the simplest plan is to cut from the center of a protecting plate 18 by 24 cm in size, an opening 5 by 7 cm or 6 by 8 centimeters This shield is applied in such a manner that the posterior margin of the submaxillary branch is barely covered (parotid gland), also the mandibular nerve and the larynx are protected The patient assumes the supine position with the shoulders raised somewhat The head hangs

loosely and is turned to one side Before the shield is applied, it is washed each time with concentrated alcohol A field back of the mastoid process remains unprotected The roentgen tube is so inclined that the central beam passes between the posterior margin of the lower jaw and the mastoid process of the side to be irradiated, and is directed toward the zygomatic process of the temporal bone on the opposite side If one desires to include adenoid growths, the beam is directed a little higher toward the orbit of the opposite side In the case of adenoids in children, the beam should be applied also to two fields reached from the back of the neck, with the patient in the prone position This technic corresponds essentially to that employed by Holfelder and Lenk

As to the dosage and the intervals between sittings, let it be stated that the single dose should be 3 H with a 0.2 zinc filter and 180 kilovolts If the patients do not live [near], one can irradiate both sides once on three successive days, and the patient can then be allowed to return home If the patients [do] reside [nearby], it is advisable to apply two irradiations each week, each side being irradiated three times The single dose may in the latter event be increased to 4 H If six weeks after the completion of the series of irradiations no evident effects are to be noted, another like series of irradiations should be applied A third series of irradiations after a further interval of six weeks is likewise admissible

It is advisable to furnish the patients with a statement covering the following points

1 The retrogression of the enlarged tonsils begins usually after from four to six weeks and proceeds gradually

2 During the first six weeks after the

irradiation, new attacks of sore throat may still occur

3 Even in the cases in which the tonsils do not diminish much in size, the predisposition to attacks of sore throat is usually eliminated within a few months

4 In about one-fifth of the cases the outcome of the irradiation is not a complete success, although some improvement can be expected in nearly every instance

It should be stated that in children the retrogression appears to be more rapid than in adults. It is important that the roentgenologist be acquainted with these details. Medical radiology has here a mission to perform, for it is important (especially in those cases in which surgical intervention is contra-indicated) that a form of treatment should be available that eliminates sore throat and its effects, particularly since the lingual tonsils and scattered tonsillar tissue about the pharyngeal ring can be influenced, whereas it cannot be removed by a surgical operation. Every radiologist must thoroughly understand the technic and must also study diligently the scientific aspects of the problem, since opposition from various sources is to be anticipated

DISCUSSION

With regard to the history of roentgen treatment of tonsillitis, K M Menzel stated that, taking as his point of departure the fact of the resorbent action of roentgen rays on lymphatic tissue, he began, as early as 1909, the systematic treatment of chronic tonsillitis by roentgen irradiation of the tonsils. A patient so treated was presented by [him] at the session of the Vienna Laryngologic Society, Dec 6, 1911. The patient was a man aged 30, who complained of frequently recurring sore throat, thick speech, snoring, and dyspnea. Examination had revealed greatly enlarged tonsils, which were in a condition of chronic inflammation

The speaker asked Prof Gottwald Schwarz, who was at that time the roentgenologic specialist for the sick benefit association, to undertake the roentgen irradiation of the patient's tonsils. At first the speaker planned to carry out the treatment by way of the mouth, and for that purpose had cylindrical metal tubes constructed which enabled the operator to confine the beam of rays to the tonsils and to shield the adjacent parts from the action of the roentgen rays. The patient was irradiated about ten times at intervals of fourteen days, the tubes just mentioned being employed. During this period of treatment, no striking effects of the intervention were observable. Not until Dr J Robinson undertook an irradiation of the tonsils from without, through the tissues overlying the two submaxillary angles, was an extensive shrinking of the tonsils brought about in September, 1910, with the result that the tonsils then presented approximately the size that the age of the patient would lead one to expect. A comparison of the condition of the tonsils before and after treatment showed a *reduction* in size equivalent to about three-fourths of the original volume. There are two things important to note: (1) That the tonsils, from the time the treatment was completed up to the time the case was presented, a period of more than one year, had not increased in size, and (2) that the formerly frequent attacks of sore throat had ceased since the beginning of treatment, a period of more than two years. Menzel closed his account with the statement that the method he had described appeared to be suitable for the elimination of not only tonsillar hypertrophy but also of the frequent recurrences of sore throat and peritonsillar abscesses that go hand in hand with chronic tonsillitis—especially in such patients as have an inordinate dread of operations or for whom tonsillectomy is contra-indicated because of the likelihood of severe

hemorrhages (hemophilia) or because of advanced age Menzel had, later, several other patients with tonsillitis or with adenoid growths irradiated by Dr Robinson. Although the results were reasonably satisfactory and the speaker still kept the subject in mind, there were three reasons why he could not continue to devote himself so intensively to the method (1) Because the treatment, as shown by the experiences at that time, covered too long a period (about nine months), (2) because the results could not be judged with absolute certainty in view of the fact that, even in severe tonsillitis and frequent recurrences of inflammatory conditions, remissions extending over several years are observed, and (3) because, at that time, owing to the exaggerated trend toward tonsillectomy, the result of American influence, the radical operation on the tonsils was universally demanded.

The speaker considers the irradiation method for the treatment of tonsils as still applicable and capable of giving good results, and he welcomes the endeavors of Schwarz and Kriser, with whom he will be glad to co-operate, more especially as many of the disadvantages of earlier days no longer exist, for example, the duration of treatment has become much shorter, the results can be measured with some degree of certainty, and we are not all of us to-day so enthusiastic about tonsillectomy. Hence, the speaker thinks he is safe in assuming that the treatment of chronic tonsillitis and of tonsillar hypertrophy with roentgen rays has a favorable future.

DR R KIENBOCK The new procedure will without doubt gradually replace operative treatment, because it offers not only greater advantages but also promises permanent results.

THE VARIOUS CAUSES OF DRYNESS IN THE MOUTH

DR J BORAK If after the irradiation

of both sides of the face the sense of dryness arises in the buccal cavity, it would appear, from our physiologic conceptions, practically certain that it is due to the diminished secretion of saliva resulting from the reduction of the activity of the salivary glands brought about by the irradiation. It is unquestionably true that the roentgen rays may reduce the functioning of the salivary glands, but there are a number of observations that seem to indicate that the sense of dryness arising after irradiations is not caused in every case by diminished secretion of saliva.

First, it will be recalled that the feeling of dryness in the mouth arises in connection with various local disorders of the buccal cavity and the pharynx and associated with various general conditions, although there is absolutely no evidence of a reduced secretion of saliva in these affections.

If the buccal cavity lies within range of the rays, it is surprising that at times when the patient complains of a marked sense of dryness, which can be relieved only by the ingestion of large quantities of fluids, an objective inspection reveals that the buccal cavity is moist throughout, in fact, one sometimes even observes considerable saliva in the form of the well known long-drawn-out threads.

This discrepancy between the subjective sensation and the objective findings becomes still more striking when we are confronted with the task of reducing in an objectively demonstrable manner the secretion of saliva. Such actual problems arise, as is well known, in fistulas of the salivary ducts, in which the activity of a normal salivary gland must be entirely suppressed, furthermore, in certain sequels of nervous and cerebral disorders (for example, in Parkinson's syndrome), in which the increased activity of both salivary glands must be reduced to normal. When we have such cases to treat, we observe that doses which suffice for the pro-

duction of the sensation of dryness are by no means sufficient for an objectively demonstrable reduction of the activity of the salivary glands. As in the treatment of hyperhidrosis, the irradiations in the latter case must often be applied with a very high dosage. Moreover, in the treatment of hyperhidrosis we do not see why the patient should complain of dryness when the hands are objectively still moist.

With reference to the treatment for increased salivation, we have another instructive observation to report. One or two days after the irradiation, there develops a sense of dryness, which lasts about a week, but not until the sensation of dryness has entirely disappeared is an objectively demonstrable diminution of the secretion of saliva in evidence. This not only begins later but also continues longer than the sensation of dryness.

From all these observations one is forced to conclude that the sensation of dryness in the mouth is brought about not indirectly through the reduction of the activity of the parotid gland but, rather, through a direct influence of the roentgen rays on the mucosa of the buccal cavity. It is well known that there are in the mucosa many branches of terminal nerves. The sensation of dryness following the irradiation of the buccal cavity is doubtless due to changes in these receptive sensory terminals. Further support for this view is furnished by the observation that I had the opportunity to make last year, since we have been using the Coutard method for the treatment of tumors of the buccal cavity. During the series of irradiations, there develops in the patients, in absolutely every case, a considerable disturbance of the sense of taste, so that the patients, for about two weeks, are unable to distinguish between sweet and salted foods.

A disturbance of the sense of taste occurs when each half of the face has received about 1,000 r, whereas a sense of dryness arises after doses of 350 r for each half of

the face. Since smaller doses are used for the treatment of chronic tonsillitis, a modification of the salivary glands and also changes in the sensory nerves of the buccal mucosa can always be avoided.

DISCUSSION

DR KARL EISINGER I take the liberty of asking Prof Schwarz to tell us at this point something about the indications and the contra-indications of the method. It is quite possible that a patient who already has an appointment during the next few days for a tonsillectomy will ask us, if this mode of treatment becomes generally known, whether he is to be operated on or whether his case is of such a character that roentgen irradiation appears indicated.

DR G SCHWARZ (closing) I wish to endorse absolutely Menzel's statements, since at the time of which he speaks, which was before we had the potent, penetrating rays, the high-power energies, and the good filtration, we had to proceed very cautiously and hesitatingly, for which reason the treatment was unduly prolonged. It is quite comprehensible that the laryngologist at that time made use of the irradiation procedure only in rare cases. With reference to Eisinger's request to state the contra-indications (which I wanted to avoid, at the present time), I am now forced to speak, and will say at the start that Schonfeld and Baumbach, of the Leipzig Children's Clinic (Prof Bessau), reject tonsillectomy in children absolutely, and approve, at the most, tonsil-lotomy, that is, clipping of the tonsils. They now accept irradiation as the procedure of choice. As contra-indications Schulte mentions advanced age (above 50 years), severe infection of the tonsils when there is danger of spreading the infection, involvement of the adjacent lymphatic glands, also disturbances of the endocrine system and of the heart, nephritis, diabetes, exophthalmic.

goiter, tuberculosis, asthma, hemophilia, or general physical weakness, furthermore in speakers and singers, and, finally, recurrences after previous tonsillectomy

THE SIGNIFICANCE OF THE MINUTE-R-AFFLUX FOR THE REACTION FROM IRRADIATIONS

DR R PAPE We are familiar with a number of observations which prove that the effect of a roentgen irradiation of given dosage depends on the duration of the irradiation and the intensity of the rayage. Back in 1924, G Schwarz observed distinct differences in the roentgen reaction on the skin, with changes in the intensity of the irradiation, which he represented by a relation of 1:4. On the other hand, a number of observations with a negative result have been reported, Borak's report having been one of the most recent. This apparent discrepancy may be explained by failure to consider the significance of the minute-r-afflux, which constitutes an expression of the absolute value of the rate of the irradiation. As these matters do not appear to be generally understood as yet, it may be well to cite four recent cases which show to how great an extent the skin tolerance, with a given dosage, depends on the intensity of the irradiation.

Conditions of the Experiment—Two abdominal fields, 13 by 18 cm, 0.5 Zn + 1 Al, 180 kilovolts, 1.0 ma. (or 0.5 ma), HED 35 (or 50) cm, dosimeter, Mekapion. The left field received 2×700 r in 2×65 minutes interrupted by a 24-hour interval. That makes a total of 1,400 r in about two hours of irradiation, the minute-r-afflux 10.7 r. The right field received 2×700 r in 2×65 minutes, interrupted by a 24-hour interval, a total of 1,400 r in about six hours of irradiation, minute-r-afflux 4 r. The relation of the irradiation intensity was thus

1:3, or, more exactly 1:2.67. The patients for these and other experiments were secured from the gynecologic department of Prof Latzko, who kindly placed an experiment room in his department at our disposal.

By the following description of results it can be demonstrated unequivocally that, in perfect agreement, the reaction of the *left* (that is to say, of the *rapidly irradiated field*) is considerably more marked than that of the *right, slowly irradiated field*. The difference does not become plainly discernible until after the main reaction (the fifth to the tenth week). The left field (10.7 r per minute) presented always a dense, brown, for the most part uneven pigmentation, erythema in patches, moderate scaling, subjective itching, while the right field (4 r per minute) presented a very delicate pigmentation, with only traces of an erythema.

By further experiments it was demonstrated that, with an irradiation intensity of 10 r per minute and the introduction of a 24-hour interval, the dosage can be increased, under the foregoing conditions, to 1,600 r.

SUMMARY

The skin reaction depends to a great extent on the minute-r-afflux. With a relation of the irradiation times, and thus of the intensities, the differences in the reactions are, indeed, considerable.

The tentative practical deductions from the experiments are. With an irradiation intensity of 10 r per minute, we can give 1,400 r in one day in two equal partial doses with an interval of from three to six hours, without endangering the skin. By introducing an interval of 24 hours, even 1,600 r are well borne. With a further reduction of the irradiation intensity to a minute-r-afflux of 4 r, a further increase of the dosage is possible.

DISCUSSION

DR R KIENBOCK In the last case, the dark border of the reactive pigmentation field is to be explained by the fact that here the electric discharges of the edge of the shield struck the skin, irritated and sensitized it and induced an hyperemia

DR J BORAK Dr Pape evidently misunderstood me if he thinks that I deny absolutely the influence of the protraction of the irradiation period on the tolerance of the skin. In my analysis of the Coutard irradiation method, my observations led me merely to express the opinion that the fractioning of the dosage exerted a more marked influence on the accentuation of the tolerance of the skin than did the protraction of the irradiation. It has been found, namely, that it is possible to effect a remarkable accentuation of the dosage by merely fractioning it. Mischer and Chaoul reached identical results. To a certain extent, also, the experiments of Dr Pape confirm that the mere protraction of the irradiation period influences the skin tolerance only to a very slight degree. For, while it is true that his experiments show a distinct difference in the skin reaction in the field irradiated three times as long, yet the difference is not three times as great. In other words, it appears to me that, from the practical point of view, it is not advisable to irradiate three times as long if only such a slight difference results. The difference consists mainly in the degree of pigmentation, whereas the duration of the reaction is the same. That with a relation of the irradiation periods of 1:3 a difference in the degree of reaction becomes evident is due solely to the fact that the partial doses employed by Dr Pape were extremely high. That 700 r, with ordinary irradiation intensity, can be repeated on two successive days appears to be the most surprising result of Dr Pape's experiments. Such high partial doses are not employed in con-

nexion with the Coutard irradiation methods. With a daily dose of only 200 r, when the irradiation is applied in accordance with the Coutard method, no difference can be observed with a total dose of 2,400 r, even when the relation of the irradiation intensities is 1:4.

DR G SCHWARZ The measurements of Dr Pape, carefully carried out, are especially important because they show that, even on the basis of 10 r minute-afflux and 4 r minute-afflux, changes in the tolerance dosage may be very distinctly observed in favor of the slow irradiation, as Dr Pape very aptly has termed this mode of administration. By applying rays of weak intensity and by checking the r afflux, we get extremely close to the doses that have become known as tolerance doses for radium irradiation at a distance (so-called radium cannons). There is no doubt in my mind but that the new types of roentgen apparatus which are already completed but are not yet in general use and which are operated with 0.5 ma and are attachable to any lighting system will dispense with the radium cannons. The mathematical fixation of the dosage with the various modes of operation (strong or weak intensity, slow or rapid irradiation) is important. It has been shown that the statement that so-and-so many r are employed has no precise meaning as regards the biologic reaction unless the minute-r-afflux—a term that we cannot get around—is added. The increase of dosage required for a slow afflux is exceedingly high. That with a slow afflux we must irradiate longer goes without saying, for example, in order to obtain 400 r with a 10 r minute-afflux we must irradiate 40 minutes, and with a 4 r minute-afflux, 100 minutes. But the 400 r with a 4 r minute-afflux do not produce the same biologic reaction as the 400 r with the 10 r minute-afflux. In order to secure the same biologic reaction, we must apply about 800 r, and thus irra-

goiter, tuberculosis, asthma, hemophilia, or general physical weakness, furthermore, in speakers and singers, and, finally, recurrences after previous tonsillectomy

THE SIGNIFICANCE OF THE MINUTE-R-AFFLUX FOR THE REACTION FROM IRRADIATIONS

DR R PAPE We are familiar with a number of observations which prove that the effect of a roentgen irradiation of given dosage depends on the duration of the irradiation and the intensity of the rayage. Back in 1924, G Schwarz observed distinct differences in the roentgen reaction on the skin, with changes in the intensity of the irradiation, which he represented by a relation of 1:4. On the other hand, a number of observations with a negative result have been reported, Borak's report having been one of the most recent. This apparent discrepancy may be explained by failure to consider the significance of the minute-r-afflux, which constitutes an expression of the absolute value of the rate of the irradiation. As these matters do not appear to be generally understood as yet, it may be well to cite four recent cases which show to how great an extent the skin tolerance, with a given dosage, depends on the intensity of the irradiation.

Conditions of the Experiment—Two abdominal fields, 13 by 18 cm., 0.5 Zn + 1 Al, 180 kilovolts, 1.0 ma (or 0.5 ma), H E D 35 (or 50) cm., dosimeter, Mekapion. The left field received 2×700 r in 2×65 minutes interrupted by a 24-hour interval. That makes a total of 1,400 r in about two hours of irradiation, the minute-r-afflux 10.7 r. The right field received 2×700 r in 2×65 minutes, interrupted by a 24-hour interval, a total of 1,400 r in about six hours of irradiation, minute-r-afflux 4 r. The relation of the irradiation intensity was thus

1:3, or, more exactly 1:2.67. The for these and other experiments v cured from the gynecologic depart Prof Latzko, who kindly placed an ment room in his department at cposal

By the following description of r can be demonstrated unequivocally perfect agreement, the reaction of (that is to say, of the *rapidly in field*) is considerably more marked th of the *right, slowly irradiated field*. difference does not become plainly eable until after the main reaction (t to the tenth week). The left field per minute) presented always a brown, for the most part uneven pig tation, erythema in patches, moderate subjective itching, while the right fie per minute) presented a very delicatementation, with only traces of an ery

By further experiments it was strated that, with an irradiation inter 10 r per minute and the introductio 24-hour interval, the dosage can creased, under the foregoing conditio 1,600 r

SUMMARY

The skin reaction depends to a gre tent on the minute-r-afflux. With a ration of the irradiation times, and thus intensities, the differences in the rea are, indeed, considerable

The tentative practical deductions the experiments are. With an irrad intensity of 10 r per minute, we can 1,400 r in one day in two equal partial with an interval of from three to six h without endangering the skin. By produc ing an interval of 24 hours, even 4 r are well borne. With a further reduc of the irradiation intensity to a mint afflux of 4 r, a further increase of the age is possible

case, which the speaker referred to as unusual in this disease, induces me to give a short report of an observation of my own. The patient was two years old, with generalized periosteal apposition (*sic*) streaks of several layers on nearly all the long bones, and a leukemic blood picture. We considered the case at the time as similar to a multiple periostitis, with myeloblast anemia, as reported by Jaksch. The case was published in the reports of the Wilhelminenspital. I should like to ask the speaker what relations, if any, there are between Albers-Schonberg disease and such rare disease symptoms, with generalized periosteal thickening of the bones. The speaker has called my attention to the fact that this publication is not by Feyrter but by his predecessor, Oesterlin, and is entitled "Ein Fall von kombinierter Knochen-Bluterkrankung" (*Arch f Pathol Anat und Physiol*, 1923, CCXLVII, 588)

DR WINDHOLZ (closing) Albers-Schonberg disease has little in common with the symptomatic (reactive) osteoscleroses that appear in combination with leukemias, other than the morphologic behavior of the bones, which is in many respects similar. Albers-Schonberg disease appears for the most part in a familial form and is often congenital. It is characterized by a high degree of fragility of the bones. The anemias that accompany it are regarded as secondary manifestations. The aforementioned osteoscleroses develop after chronic leukemias, for the most part at an advanced age, and show no abnormal fragility of the bones. In a case that came to necropsy there was a chronic myeloid leukemia, with a large tumor of the spleen. The long bones were thickened and showed high-grade sclerosis; the marrow cavity and the substantia spongiosa were scarcely recognizable. In the case of Jaksch there was a periostitis without a diffuse osteosclerosis.

diate not 100 but 200 minutes. This fact is not self-evident, nor is it sufficiently known. The determination of exact relations expressible in figures is the aim and content of the Pape researches.

DR KRISER The highly pigmented border on the medial and cranial side of the irradiated abdominal field is not, in my opinion, produced by electric charges, but is, I think, caused by other factors.

I have observed on inspection that, owing to the curvature of the abdomen, these sides of the field lie nearer to the tube focus than the caudal and lateral sides of the field. Owing to the lesser focal-skin distance, this side of the field up to the borderlines covered with a lead screen receives a correspondingly greater amount of rays than the side of the field that is more distant from the focus. Secondly, the lead screens absorb the whole mass of rays and give off only at the edges that border the field the hardest rayage in the form of secondary irradiation, which constitutes a dosage supplementary to the dose applied directly to the skin.

Thus the H E D plus the lesser focal-skin distance, plus the secondary irradiation of the protective material, taken together, produce a greater linear effect, which is visible as a darker pigmented border.

Dr PAPE (closing) The deductions of Dr Borak are based on a mathematically erroneous conception. He compares the effect of irradiation given in fractioned doses over a period of two weeks with the effect of a change in intensity of irradiation in the ratio of 1:3, and reaches the conclusion that the fractioned irradiation which is superior in this special case is superior by reason of the special principle involved. With equal right, however, one might assert the opposite for example I compare the effect of a change in irradiation intensity 1:100 or 1:1,000 with the effect of a simple division of the dosage into two parts and

application with only a one-hour interval. Thus one would reach the conclusion that the change in intensity has more effect than the fractioning of the dosage. In judging the effect of fractioning the dosage, we must consider not only the total dosage but also the number of single doses and the intervals between them.

DEMONSTRATION OF A CASE OF ALBERS-SCHONBERG'S DISEASE

DR WINDHOLZ The patient was an 11-months-old child, who was referred to the Holzknecht Institute with a bilateral atrophy of the optic nerve. The child was the offspring of an incestuous connection. In addition to the high-grade atrophy of the optic nerve, there was a mild anemia, a square-shaped head, and a rigid thorax. The roentgenologic examination revealed a marked increase of the thickness and likewise the density of the bone-marrow spaces, whereas the substantia spongiosa was not recognizable. The metaphyses were swollen and knotted and dark transverse streaks passed through them. There was no disturbance of ossification and no fractures. Periosteal apposition (*sic*) streaks were visible on the inner surface of the tibia and the ulna. The Wassermann test was negative. There was a hereditary malformation of the skeleton. A simultaneous disturbance of the phosphorus metabolism was not to be excluded.

DISCUSSION

DR R KIEVBOCK The disease in children was first described in detail by Laurell and Wallgren, in 1920, under the name "osteosclerosis infantilis generalisata fragilis". In the present case, strange to say, no fractures were observed.

DR F FLEISCHNER The observation of periosteal apposition (*sic*) streaks, in his

92), the court held that the Industrial Commission had no jurisdiction over the amount of Dr Hoyt's fee, as the latter had not elected to come under the compensation law.

Still another decision is cited from the same court, in which an employer had engaged a Centralia physician to care for an injured employee and refused to pay the bill for same, claiming that the fixing of the amount of the fee should have been done by the Industrial Commission.

In this decision the Court said "We find nothing in the Workmen's Compensation Act that makes it obligatory upon a physician who is retained by an employer to treat his injured employee, to submit his claim for such services to the Industrial Commission for its determination, nor is jurisdiction conferred upon said Commission to do so. In our opinion the court properly sustained

the demurrer to the plea and the judgment should be affirmed."

In a case before the Indiana Court of Appeals—*Sullivan vs The National Car Coupler Co* (Ind.), 126 NER 494, 73 Ind App 442—almost identically the same decision as the last two was rendered.

Reasoning from the foregoing reviewed and decided cases, it would seem that we are fully justified in the statement that the industrial commissions or boards have no jurisdiction, and, in fact, nothing whatsoever to do with fixing the amount of the fees of physicians in industrial injuries or for services to patients of any sort or character, and we are not and cannot be made to be controlled or regulated as regards the amount of our fees in this or any other particular by these bodies.

CASES OF INTEREST TO RADIOLOGISTS

ROENTGEN INJURY AS EVIDENCE OF NEGLIGENCE IN A DIAGNOSTIC PROCEDURE

Ragin vs Zimmerman (Calif.), 276 PR 107

A nurse employed by the defendant, Zimmerman, a dentist, tried to take a roentgenogram of the plaintiff's chin. The plaintiff was electrically shocked and burned in the process. From a judgment in his patient's favor, Zimmerman appealed to the Supreme Court of California. In his appeal, he assumed that the doctrine of *res ipsa loquitur* had been applied in reaching a verdict against him, and he combated the application of it to malpractice cases. The Supreme Court found nothing in the record to indicate that the trial court was influenced by that doctrine, but it did find that the cases cited by the defendant to show that the doctrine was not applicable in malpractice cases brought against physicians, surgeons, and

dentists for errors in the treatment of disease had no application in the present case, because the appellant was not employing the roentgen rays for treatment when his patient was injured. While the Supreme Court found no reason for applying the doctrine to the present case, the Court would not hesitate, it said, to apply it to the facts described by the evidence if there were occasion for doing so. It quoted with approval *Evans vs Clapp* (Mo App.), 231 SWR 179, as follows:

As hereinbefore stated, the X-ray was not applied in this case for purposes of treatment but merely to ascertain the cause of plaintiff's headaches, and this was disclosed at the first examination. There is no room, therefore, for the application of a treatment intended to be applied in the accomplishment of a result similar to the one produced but not to the extent thereof. On the contrary, the X-ray was to be used only to discover a condition which was at once shown, and the many other exposures were not made in the interest of the patient,

MEDICO-LEGAL DEPARTMENT

FEES

INSURANCE COMPANIES OR INDUSTRIAL COMMISSIONS HAVE NO JURISDICTION
OVER MEDICAL FEES

By I S TROSTLER, M D, F A C R., F A C P., CHICAGO

The question as to whether physicians or surgeons must accept such fees as are fixed in amount by industrial commissions or insurance companies has come up several times in discussions in the writer's presence and he has been asked about it by radiologists in Wisconsin, Indiana, Ohio, Pennsylvania, and Illinois.

In each of the replies to the eight radiologists who have asked this question he has replied, that, as far as he has been able to learn, the industrial commissions in the States named have no more right to fix medical, surgical, or radiological fees than they have to regulate the width of sidewalks or the weight of watermelons. In Illinois it has been decided in several cases which were appealed from the courts of original jurisdiction that "The Industrial Commission has no power as between the physician and his patient, to determine the amount of the fee to be charged for any medical service. In the absence of a contract between the physician and the patient regarding the amount of the fee, the physician may collect a fair and reasonable fee for his services, any finding, ruling, regulation, or decision by the Industrial Commission to the contrary notwithstanding."

In *Noer vs George Jones Lumber Co* (Wis.), 175 N W R 784, 170 Wis 418, the Wisconsin Supreme Court said "The Workmen's Compensation Act deals exclusively with matters growing out of the relation between employer and employee. The provisions of that Act are binding upon employers and employees electing to be bound by them, and upon none others. All except

employers and employees are strangers to the Act, and their usual lawful rights and remedies are unaffected by it."

In a case appealed to the Illinois Court of Appeals, the verdict of the lower court (in favor of a physician who sued for his fee) the defendant in the original trial claimed and contended that the Industrial Commission had the right to fix the amount of medical and surgical fees in industrial compensation cases. In rendering its decision in favor of the physician the Court said "The question to be decided is whether it was the intention of the legislature, in the enactment of the provisions on which the defendant relies, to take away from the employer and a third person (in this case the physician) their right to contract with each other. Considering the whole Act in connection with these provisions, we think it is apparent that such was not the intention of the legislature. The theory upon which our Compensation Act is based is that the parties to whom it applies—the employer and his employees—must voluntarily elect to come under its provisions. It is when they have so elected that the Act deprives the courts of their jurisdiction to enforce contractual terms between them. The manner in which they shall come under the Act is the same by which physicians, if they elect, may voluntarily come under its provisions."

This consideration has been held to be controlling in the construction of similar statutes in other States.

In another Illinois Appellate Court case (*Hoyt vs London Guarantee and Accident Co* and *Nokomis Coal Co*, 227 Ill App

usually manifests itself after the first treatment and occasionally after the second, but none of them had ever seen a case after the third treatment. The Supreme Court, therefore, concurred in the opinion of the Court of Appeals that the burn in this case could not have resulted from an idiosyncrasy.

There was evidence to show that the defendant did not uncover and examine the area to be treated on the occasion when the burn was inflicted. Concerning this, one of the expert witnesses said "Just because a patient has stood a certain amount of roentgen-ray therapy on previous occasions is no criterion by which the doctor can be guided as to future treatments. The area to be exposed ought always to be examined before exposure is given."

The occurrence of a roentgen-ray burn, even after 160 treatments had been safely given, would indicate, this witness testified, "that before the last exposure was given there was a definite indication upon the surface of the skin which even to the semi-trained eye would indicate that he was treading on dangerous ground, or second, that there was some mistake of the technic or some error of judgment in giving the amount of the exposure that was given at that time, which was sufficient in itself to cause a roentgen-ray burn of the severity as described."

The Supreme Court concurred in the opinion of the Court of Appeals that under the doctrine of *res ipsa loquitur* there was sufficient evidence to take this case to the jury. The Supreme Court quoted 20 R C L 187.

More precisely, the doctrine *res ipsa loquitur* asserts that, whenever a thing which produced an injury is shown to have been under the control and management of the defendant, and the occurrence is such as in the ordinary course of events does not happen if due care has been exercised, the fact of injury itself will be deemed to afford sufficient evidence to support a recovery, in the absence of any ex-

planation by the defendant tending to show that the injury was not due to his want of care.

The reason generally assigned for rejecting the doctrine of *res ipsa loquitur* in a case such as that before the court is that it does not take into account the idiosyncrasy of the patient, which is occasionally responsible for the burn. In this case the conclusion seemed inevitable that the burn could not have resulted from an idiosyncrasy. *Res ipsa loquitur* means merely that the facts warrant the inference of negligence, not that they compel such an inference. They furnish circumstantial evidence of negligence where direct evidence may be lacking, but such circumstantial evidence is to be weighed, not necessarily to be accepted as sufficient. It calls for explanation or rebuttal but does not necessarily require it. It makes a case to be decided by the jury but does not forestall the verdict. When all the evidence is in, it is for the jury to determine whether the preponderance is with the plaintiff.

The action of the Court of Appeals in reversing and remanding the case for a new trial was correct, and the petition for the defendant for a writ of *certiorari* was therefore denied.

LIMITATION BEGINS TO RUN WHEN TREATMENT CEASES

Schmitt vs Esser (Minn.), 226 N W R 196

In malpractice cases there is difficulty in determining the precise moment when the act or omission which caused the damage took place. The neglectful or unskillful act may occur at some particular moment during months of attendance on the patient, or it may persist and characterize the whole treatment. It would seem advisable, therefore, not to apply the bar of the statute of limitations unless it clearly appears from the complaint that the unskillful or negligent act which caused the injury antedated the action by a period greater than the statutory pe-

but for other purposes Examinations, when carefully and properly made, do not produce burns, hence when a burn is produced, this fact is of itself some evidence from which the jury may find that the degree of care and skill ordinarily exercised by persons of like profession and using such agencies was not exercised in that particular case *George vs Shannon*, 92 Kan 801, 808, 142 P R 967, Ann Cas 1916B, 338, *Shockley vs Tucker*, 127 Iowa 456, 103 N W R 360

The judgment of the trial court in favor of the injured patient was, therefore, affirmed

FAILURE TO USE ROENTGEN RAYS IN REDUCING FRACTURE IS VERY COSTLY TO PHYSICIAN

Stoll vs Balasz (Ohio), 167 N E R 522

A kick by a horse fractured the tibia and fibula of the patient's left leg Stoll, a physician, attempted to reduce the fracture, but at no time in the earlier stage of his employment did he use roentgen rays to guide him in diagnosis and treatment According to the record, a ligament or tendon got between the ends of the broken bones and prevented union When roentgen rays were finally used, they disclosed a space of from three-sixteenths to one-half inch between the ends of the bones This, according to the record, resulted in an infection and sloughing off of bone, so that plates had to be used to bring the ends together to procure union Ultimately there was a shortening of the leg There was evidence to show that it was the customary and usual practice to use roentgen rays in the reduction of fractures, and, while they would not show a ligament or tendon between the ends of fractured bones, they would show that the bones had not been properly set so as to permit union There was evidence to show, too, that the ultimate process of curing the infection and procuring union was exceedingly painful and that the patient's crippled condition was

permanent The jury returned a verdict in favor of the patient for \$20,000 On appeal by the physician, however, the Court of Appeals of Ohio, Cuyahoga County, concluded that the verdict was excessive The jury, said the Court, probably took into consideration the pain and suffering that the patient had to endure by reason of the horse's kick which was no part and could be no part of a judgment rendered against the attending physician, because he was in no way responsible for it Nevertheless there was ample evidence to justify a verdict against the physician It was ordered, therefore, that the judgment of the court below be reversed unless the patient remitted \$5,000 of the verdict and accepted \$15,000 in settlement

RES IPSA LOQUITUR IS MADE TO APPLY IN ROENTGEN DERMATITIS

Lewis vs Casenburg (Tenn), 7 S W R (2d) 808

"The area to be exposed (treated) ought always to be examined before exposure is given"

The defendant, Casenburg, administered 161 roentgen-ray treatments to a Mrs Lewis, extending over a period of six years After the last treatment a third degree dermatitis appeared on her abdomen, covering a space of 7 by 9 inches and sloughing off "practically to the lining of the intestine" Mrs Lewis died, but whether from the effects of the injury or from some other cause the record does not show Her administrator sued to recover damages for the injury done by the burn The trial court directed a verdict for the defendant The Court of Appeals, however, reversed the judgment of the trial court and remanded the case for a new trial Thereupon the defendant petitioned the Supreme Court of Tennessee for a writ of *cetiorari* in order to obtain a review of the case by the court Practically all of the experts testified that idiosyncrasies

INTERPRETATION OF ROENTGENOGRAMS

Appleby vs Cass (Iowa), 229 N W R 210

Appleby's right temple was injured in a collision between an automobile driven by him and an automobile owned by Cass. He sued Cass. In the course of the trial, one of Appleby's physicians undertook to explain to the jury the significance of various features of a roentgenogram itself offered in evidence. Counsel for Cass objected, asserting that this was not proper testimony and that the roentgenogram itself was the best evidence of what it showed. The objection was overruled. The jury rendered a verdict in favor of Appleby, and Cass appealed to the Supreme Court of Iowa.

In *Elzig vs Bales*, 135 Iowa 209, 112 N W R 540, the Supreme Court of Iowa held that a photograph was itself the best evidence of what appeared in it, and in *Lang vs Marshalltown L P & R Co*, 185 Iowa 940, 170 N W R 463, it applied the same rule to a roentgenogram offered in evidence to show a curvature of the spine, the question being only whether it showed a straight line or a curved one. In the latter case the roentgenogram served a purpose similar to that of a photograph. In *Daniels vs Iowa City*, 191 Iowa 811, 183 N W R 415, 416, however, the Court opened the door to expert evidence offered for the interpretation of a roentgenogram, saying:

It is proper for an expert to explain an X-ray photograph in such particulars that are not understood by a layman. (See *State vs Matheson*, 142 Iowa 414, 120 N W R 1036, 134 Am St Rep 426.) What the jury could see and understand about the matter is not the subject of expert testimony, and this we understand to be the effect of our prior decisions. A radiograph may be used for purposes of demonstration by an expert as though he had the object itself before the jury for explanation (*Sheldon vs Wright*, 80 Vt 298, 67 A P 807).

The Supreme Court might properly, it

said, take judicial notice of what is well known to the profession, namely, that a roentgenogram does not necessarily or ordinarily interpret itself to the observation of a non-expert. A roentgenogram carries various lights and shadows the significance of which is known to the expert and is not known to the non-expert. In the present case the purpose of the roentgenogram was to show the existence and location of a "perforation of the temple." The physician in the case had diagnosed "hole" in the temple. This "hole" was indicated by the experts by certain characteristics of light and shadow in the roentgenogram. It was not observable as a "hole" on the ordinary scrutiny of a non-expert. The purpose of the expert testimony was to explain the meaning of the lights and shadows in the roentgenogram. Such an explanation was essential to a proper understanding of it and the admission of expert testimony for that purpose was proper. Only when a roentgenogram is offered in evidence to serve nothing more than the function of a photograph is it subject to the rules of evidence applying to photographs.

The judgment of the trial court was reversed, however, on grounds not pertinent to the subject matter of this abstract.

COLLECTION OF PHYSICIAN'S FEES FOR SERVICES TO INJURED WORKMEN

Wilson Drilling Co vs Beyer (Okla), 280 P R 846

The Workmen's Compensation Act of Oklahoma, says the Supreme Court of Oklahoma, is not concerned with claims against employers, except such as are incident to pending claims of workmen or their dependents, for compensation based on injuries to workmen. Medical services are covered by the Act only as they are ancillary to its prime purpose, relief for the injured employee. A physician treating an injured

riod of limitations "We think," said the Supreme Court of Minnesota, "that the treatment and employment of a physician should be considered as a whole and that, in event of malpractice, the statute of limitations begins to run when treatment ceases."

DEATH FROM ROENTGEN INJURIES

Hess vs Rouse (Texas), 22 SWR (2d) 1077

The defendant, Hess, a physician, administered three roentgen treatments. The first was applied to his patient's abdomen. A few days later a treatment was applied to her back, followed in a few days by the third treatment, also to her back. In a short time, apparently after the last treatment, a third degree dermatitis developed covering an area of about 4 by 7 inches. The tissues under the burned area sloughed off "down to the lining of her intestines," and the patient died. Her husband and children brought suit. Judgment was rendered against the defendant for \$8,467.50. He appealed to the Court of Civil Appeals of Texas (Austin), where the judgment was affirmed.

Physicians testified that a third degree burn is ordinarily the result of (1) administering roentgen rays of too great strength, (2) not focusing at the proper distance, (3) continuing the treatment for too long a time, (4) using the roentgen-ray machine without a proper filter, or, at all events, a failure of the physician to observe some established method or rule of administering roentgen therapy. Testimony was offered to show that occasionally a patient possesses an idiosyncrasy or supersensitiveness with respect to roentgen rays and is more liable to be burned than is the ordinary patient. The existence of an idiosyncrasy in the present case, however, said the Court of Civil Appeals, was fairly negatived through testimony showing that when an idiosyncrasy exists it extends alike to all parts of the

body and is ordinarily detected in the first or second treatment. The deceased was burned from one of the treatments, but not from the other two. The evidence was sufficient, said the Court, to warrant the jury in finding that the defendant failed to use the reasonable degree of care, skill, and diligence in treating the deceased with roentgen rays that is ordinarily used by the average members of the medical profession in good standing in the community where the injury occurred, under the same or similar circumstances, and to warrant it in concluding that such failure was the direct and proximate cause of death. This, said the Appellate Court, is the test of liability in a case of this character.

The defendant moved for a new trial, alleging that he had discovered after the trial that another physician had applied "Iodex" and "Antiphlogistine" to the burn on the body of the deceased, applications contra-indicated in roentgen burns and which, if used to any great extent, cause a breaking down of the tissues and lead to the death of the patient. The defendant, himself, however, treated the deceased until her death. Certainly, said the Court, he should have detected any improper treatment by other physicians, who occasionally treated the deceased in his absence. The plaintiffs, when they started this suit, admitted that they had employed other physicians to treat the burn, and common reason should have suggested to the defendant that it was important for him to ascertain what medicine had been used by them. The evidence shows simply that the defendant did not exercise any degree of diligence to obtain such information. As one essential to granting a new trial on the ground of newly discovered evidence is that the party asking for a new trial could not have obtained such evidence by a reasonable degree of diligence before the trial, the trial court did not err in overruling the defendant's motion.

The primary purpose of the statute is not, however, to provide compensation to physician, but solely to provide compensation to the injured employee for such medical service as the law permits him to procure at the expense of his employer. It does not, therefore, provide for any award to a physician, but merely gives the physician a lien upon the compensation awarded to the workman, which "shall be paid therefrom only in the manner fixed by the Commission"

Because the claim filed by the physician in the present case could not be considered by the Industrial Commission in the absence of a claim for compensation filed by the injured workman, and because the injured workman had not filed such a claim within the time limited by law, one year after the injury, the Supreme Court reversed the order of the Industrial Commission awarding the physician compensation for his services and directed the Commission to dismiss his claim

WORKMEN'S COMPENSATION ACTS

"ACCIDENT" DEFINED

Carr vs Murch Bros Const Co (Mo), 21 SWR (2d) 897

An unexpected and unforeseen result of a usual and intentional act or movement done in the ordinary course of employment is an accident within the meaning of Paragraph (b) of Section 7 of the Missouri Workmen's Compensation Act, which defines "accident" as meaning "an unexpected or unforeseen event happening suddenly and violently, with or without human fault and producing at the time objective symptoms of any injury"

The strangulation of an old hernia, that resulted from reaching up in the ordinary course of employment to manipulate a steam valve, is an accident within the meaning of the law, and the injured employee is entitled to compensation, according to the Missouri Supreme Court

employee may resort to the courts for the collection of his claim either against the employer who authorized his services or against the employee to whom they were rendered. The Industrial Commission cannot hear and determine a physician's claim for payment for professional services to an injured employee, unless the employee has filed with the Commission his claim for compensation.

In the present case the appellee, Beyer, filed with the Industrial Commission more than two years after the injury an attending physician's report showing that he removed a piece of steel from the right eye of an injured employee of the appellant. The injured employee filed no claim for compensation and no award was made to him. The Industrial Commission, however, awarded his attending physician, Beyer, \$100 for his professional services. The employer thereupon appealed to the Supreme Court of Oklahoma.

The question presented, said the Supreme Court, is whether proceedings to recover payment for professional services in treating an injured employee can be instituted by a physician independent of proceedings by the employee to recover compensation for the injury or are necessarily supplementary to proceedings instituted by the injured employee, in other words, can the claim of the physician, standing alone, be heard and determined by the Industrial Commission, or is it necessarily relegated to the courts of law? The Supreme Court quoted Robinson *vs* Taylor, 116 Okla 131, 244 P 44, 47, in which an award had been made for the benefit of a physician and a hospital, ancillary to the main case, and in which the Court said:

It was further contended that the Commission was without power to make an award direct to the doctor and the hospital. The contention is correct, and if, independent of the main case, the doctor had presented his claim or the hospital had presented its claim, we

should say that the Commission had no jurisdiction.

In *Scruggs Bros & Bill Garage vs Commission*, 94 Okla 187, 221 P R 470, 475, question arose as to the right of the Commission to make an award direct to the physicians who had treated an injured employee. The injured employee, who was claiming compensation on his own account, had not paid the physicians for their services and a claim for payment for medical services was therefore filed independently of his claim. In that case it was held that it was not improper nor beyond the authority of the Industrial Commission to award both claims to the injured employee, but the Commission should have declared a lien on the amount awarded the injured workman, in favor of the physician-claimants, for the amount found to be due them. The Court said:

We think the Commission was in error in making this supplemental order for two reasons, the first being that claims arising under the workmen's compensation law are matters strictly arising between the injured employee on the one side, and the employer and his insurance carrier on the other. Differences between the employer and his insurance carrier and third persons are not cognizable before the Industrial Commission.

In *Associated Employers' Reciprocal vs Commission*, 87 Okla R. 16, 208 P R 798, 801, the Court said:

But where the employer voluntarily furnishes medical services, it is a matter of contract solely between the employer and the physician, and the Industrial Commission has no jurisdiction of such matter. But where controversy arises, the parties are relegated to the courts for an adjudication of the matter.

In *Bloom vs Jaffe*, 94 Misc Rep 222, 157 N Y Supp 926, 927, it was held

apparatus, and increased accuracy and efficiency of therapeutic dosage, all are the fruits of painstaking research. But in all this enthusiasm in building a fine healthy youth, I fear we have been remiss in teaching him some of his manners, so that he may appear in respectable society without embarrassment to his elders. I believe you apprehend my meaning that it is most necessary that this young specialty be made to occupy the dignified relation to the general medical profession and public which its importance warrants.

Let us look briefly over the life of this growing youth from the beginning up to the present, review some of the important influences that have had an unfavorable effect upon his life, analyze them briefly, and finally try to offer some suggestions for improving this situation, with the object that this specialty may deservedly occupy a more dignified position than it appears to have occupied up to the present moment.

One of the most important unfriendly factors that we have to face is the attitude of our medical practice laws. Beauty parlors, shoe stores, laymen, chiropractors, and all sorts of parasitic growths that have attached themselves to the medical body, are allowed to use the roentgen ray at will and without hindrance. The implication is obvious, that the practice of radiology is not the practice of medicine. What a great injustice, that a medical law may say that a person not duly qualified may not legally prescribe a dose of quinine, which, if you give too much, causes only an unpleasant ringing in the ears, but that anybody, qualified or not, may administer a dose of the roentgen ray, which, if too large, may do irreparable harm.

It is hard sometimes to understand why medical laws appear in so many instances to have an unfriendly attitude toward that great body of the medical profession, which is doing so much for the relief of the suffer-

ing of mankind. Perhaps this is not difficult to understand when one has had occasion to meet certain units of the legislative bodies that are making the laws, that are manifestly swayed either by the weight of their own ignorance or by a prejudice cultivated in them by some of the groups of medical parasites whose mental mechanism, being more nearly of the same caliber as their own, impresses and influences them more easily.

Several years ago two prominent radiologists of San Francisco and I made a pilgrimage to our State capitol to remonstrate with a certain committee that was contemplating a law to license lay radiographers. It certainly was far from an exhilarating and encouraging experience to find the laws governing the practice of a learned profession being manipulated by men who had positively no conception of the principles with which they were dealing, and who were obviously laboring under the pressure of forces quite inimical to the medical profession. By some unaccountable mistake, a legislator who was a member of our own profession was on that committee, and he proved our only salvation in this case.

What can we do about this? Medical laws, particularly as they affect the radiologic profession, must eventually be changed. This Society has its Legislative Committee which has been active. It deserves our whole-hearted co-operation.

I sometimes wonder, however, if the medical profession may not have participated too deeply in legislation at times, and may not have come out of it without much gain.

It has at times seemed necessary to organize certain bodies with the express purpose of taking an active part in politics insofar as they touch on medical legislation. These organizations have done some good work, but I can never forget the time when a large and prominent state medical society was on

WHITHER THE RADIOLOGIST?¹

During my perusal of the periodicals devoted in whole or in part to radiology, I have been impressed in recent weeks by the frequent appearance of articles and editorials dealing, not with the scientific side, but, let us say, with the sociologic and economic phases of our specialty. Since these same phases have been a great deal upon my own mind, I resolved that I would make an effort to focus a discussion on this subject.

Many of the leaders in our science have expressed their concern, in print and otherwise, over the status of our specialty, and I was interested to see, in the minutes of the last meeting of the American College of Radiology, the record of an extended discussion of this subject.

There must be some reason for this matter coming up in the minds of so many of us who are so widely separated over the country. It must mean that many of us feel that there is something in our menage that needs adjustment, that there are some common evils in our profession that are general, no matter in what location we are practising.

These articles have dealt generally with the status of the radiologist, both in hospi-

tal and private practice, his relation to the other branches of medical practice, and the general trend of the estimation of his work by these other branches. The question has been asked, "Is radiology moving toward complete recognition as one of the most highly specialized branches of medicine and surgery, or is it being hampered in its progress by certain conditions and influences which have been ignored or disregarded too long?"

No apology is necessary for the introduction of this topic into a session otherwise devoted to purely scientific deliberations. It will do us no harm to glance up occasionally from our absorbing scientific investigations to take a view of the horizon and the stars, get our bearings, so to speak, then we can return to our browsings for a while longer.

We assume with assurance that our specialty is an honorable one, one eminently worth while, that it deals with a most fruitful source of information in the *diagnosis* of disease, and with one of the most potent of all principles in the *therapy* of disease, that it touches intimately every other branch of medical practice, from the standpoint of both diagnosis and therapeutics.

Radiology is a relatively young science, and for that reason it may display many of the frailties of youth, but I dare say also that radiology displays much of youth's vigor, enthusiasm, and vision. Those of us who have dedicated our lives to this young science would like to feel that we are doing our best in every way to further its progress and to enhance its usefulness. Many of our number are performing wonderful service in making this youth grow to a strong lusty man physically, that is, rapid strides are being made in the *science* of radiology. New and valuable diagnostic methods, perfected

at the Sixteenth Annual Meeting at Los Angeles, California
Dec. 1-5, 1930

cal and professional sides of the work Better no X-ray service at all than one used in the casual manner prevalent in many general practitioners' offices

In my early years of general practice I remember well hearing a prominent diagnostician, for whom I had great admiration, say that he made all his own observations of the eye grounds, whereupon I immediately purchased for myself an ophthalmoscope After trying for a while to use it, I laid it aside and never used it again, preferring to have the ophthalmologist do that work for me, and deciding that either I was very stupid, or my internist friend was not so smart as he thought he was

However, our attitude toward the general practitioner who is trying to do some X-ray work should be one of friendly sympathy and helpfulness Nothing is to be gained by a spirit of resentfulness to the invasion of our special field The physician should be encouraged to bring his films to us for examination and advice Nothing will convince him sooner of the fallacy of the idea that the practice of radiology is a simple affair, to be mastered after a few days of instruction from a salesman

The disposal of the films taken in the course of roentgen-ray examination is also open to discussion The value of the film itself is too often unduly stressed It is my opinion that the X-ray films are for the use of the profession only, and that the placing of the films in the hands of patients or friends, following an examination, only tends to encourage the idea that it is films they pay for instead of a medical opinion This practice exposes the patient further to the injustice of having these films interpreted by unqualified persons, and in some instances to being led to unnecessary and even dangerous treatment

The compensation insurance companies are offenders in basing their compensation to the radiologist on the number and size of

films taken I will confess that it ruffles me not a little every time I am required to stipulate these figures, as though we could deal out roentgen diagnosis by the square inch I realize the obvious fact that frequently a vastly more important diagnosis, both to the patient and to the insurance company, is made from the evidence on a small 5×7 film than in another case on several 14×17 films

Such conditions as these tend to put the roentgen laboratory on the basis of a photograph gallery Some time ago this fact was brought very forcibly to my mind, when the operator in a prominent local photograph studio was referred to me for X-ray examination When he appeared for the work, he began by asking me in all seriousness if there would be a professional discount

The most serious blot on the name of the science of radiology is the lay laboratory, and its attendant ills It is largely the outgrowth of the laxness of our medical laws, combined with the short-sighted, selfish attitude of a certain proportion of the medical profession

The X-ray laboratory, run solely by lay hands and catering to the undiscerning of the medical profession, is an almost unmixed evil No less so is the laboratory to which a graduate in medicine, forgetting the high ideals of his profession, has lent his name, in order to give it a semblance of respectability, but in which he takes no directing part whatsoever

Most pernicious and disgraceful is the laboratory, whether lay, professional, so-called "co-operative," or what you will, that participates in that subtle form of fee-splitting known as the rebate It is a peculiar mental quirk that will permit a physician in good and honorable standing in his local and national medical associations to hold up his hands in holy horror at the suggestion of splitting a fee with another physician, yet

the point of organizing the lay technicians of the State into a society, to be associated with itself, the movement being largely fostered by a political organization allied with the state medical society. This plan did not succeed, due to the active efforts of some very wide-awake radiologists in that society. It is only fair to say that this was several years ago and probably would not happen now.

While I repeat most emphatically that our present medical laws are unjust in respect to the radiologic profession and must be eventually changed, I am not advocating active campaigns for the change of these laws at the present time, because I believe there are conditions closer at home which should be remedied first.

I believe we have also been done an injury, unintentionally, no doubt, by the efforts of assiduous salesmen of X-ray apparatus. Urged by pressure from the sales manager and the very pardonable desire for commissions and advancement, they have canvassed the entire medical profession, both regular and quack, and succeeded to no small degree in persuading a goodly proportion of the profession that the ownership of X-ray apparatus, plus a few instructions from the salesman as to the location of certain switches and buttons, constitutes them full-fledged radiologists. These salesmen have appealed to the very natural desire for financial gain by painting glowing pictures of the marvelous prosperity of those engaged in radiology (*sic!*), and have loaded some of them with an array of apparatus and accessories that would bewilder many an experienced worker.

Hear this excerpt from the advertisement in a leading surgical journal, of one of our large manufacturers of X-ray apparatus: "Apparatus so perfected that its safe and satisfactory operation requires no specialized training." Further in the same advertisement we read, "Make your own X-ray

examination!"—and then, almost sensing a recoil from some irritated radiologist, there follows, "Consult your roentgenologist in doubtful cases."

It is the experience of most of us, I am sure, that the ordinary practitioner is not aware of the confines of that borderline of doubt—doubt which often first appears to enter his mind when a patient of upwards of two hundred pounds confronts him, and he wonders if he can do the case justice with his particular machine. Needless to say, none of these suggestions appears in any of the advertisements in the radiologic journals.

Seldom are these salesmen found to advise prospective customers, in the words of the familiar automobile advertisement, "Ask the man who owns one." Too often that man would tell the physician this scheme is a snare and a delusion, that he has a white elephant on his hands that will not pay for its keep, and while he is wasting time and materials trying to get some sort of image on a film, to say nothing of learning what it means, he could advise with several patients along lines in which he is better qualified, with greater profit to the patient and to himself.

It is obvious we can do nothing about this situation. The manufacturer is bent on establishing a larger volume of business—no matter where his product goes. If this volume should result in diminished cost of apparatus, we might all benefit by it, but so far this has not happened to any noticeable degree. In full justice to our medical confrères who live within easy reach of a competent radiologist, it is only fair for the radiologist to speak frankly when his advice is asked concerning the purchase of X-ray equipment. The physician should be reminded of the great expense attached to the use of X-ray apparatus, the increased hazards, the greatly increased insurance premiums, and the necessity of conscientiously giving a large amount of time to learning the techni-

go far toward maintaining the attitude of the roentgenologist and technician toward each other as a happy one

Admitting the importance of all these external influences, there is to my mind a problem much nearer home which demands solution, the close and conscientious attention to which will go further than any one thing toward enhancing the value of the radiologist in his medical community, and bringing him to that position of recognition which the importance of his specialty deserves. Our great fault, I believe, is the position so many of us have assumed of isolating ourselves from the clinical practice of medicine. We have burned up the roads between various branch offices and hospitals on film-reading expeditions. We have seen little of our patients, except when fluoroscopy was needed, and have neglected even then to take a personal interest in the clinical side of the case. We have failed to discuss cases fully, as we should have done, with the referring physician. We have not acquainted ourselves with his problems in the particular case in which he is seeking our help. How can we expect him to consider us as consultants if we do not even see his patient, or ask for the history and clinical and other laboratory data?

Most emphatically do I assert that until we institute a very distinct reform in this practice radiology will never be considered much more than a mere incidental influence in the diagnosis and treatment of disease. Unless we renew within ourselves the realization that we are practising medicine, first, last, and all the time, we can never expect the profession or the public to recognize us as standing shoulder to shoulder in the front rank with the specializing internist, surgeon, laryngologist, and the other specialties.

In a recent issue of *RADIOLOGY* one of our members wrote a very fitting tribute to a confrère who had died in an Eastern city. Most pointed was the remark, "He was a physician practising radiology." How aptly

put! What a stinging rebuke to those of us who have fallen so far short of the full measure of our usefulness, and whose knowledge of the patient entrusted to us is too often confined to a few square inches of celluloid!

In the progress of our specialty toward maturity we shall find that more frequently the patients are seeking the services of the radiologist first hand. I am sure most of us are experiencing this already. Heretofore we have had all but a very small portion of our work referred by other physicians, and we have been largely depending on the patronage of a profession which is notoriously whimsical. (It is permissible to say this since we include ourselves with the rest.)

I believe that the opinion expressed by Dr. Groover in a recent editorial is correct. We shall find with increasing frequency that patients will seek radiologic advice and service on their own initiative or will suggest it to their attending physicians. It will consequently follow that the radiologist will himself become a referring physician. He will be directing patients to other specialists for certain services. His stock will rise noticeably then. It only remains necessary that the radiologist keep himself *clinically alive*, and maintain his touch with the progress of medicine in other lines. With strict adherence to the ethical principles, with which we are all conversant, he can pursue this course with perfect justice to his referring clientele, and grow in respect and usefulness. He must prepare himself to discuss intelligently, in staff and medical society meetings, all cases that he has contacted or that concern his work, and by "intelligently" I mean with the ability to realize the clinical significance of the case. It is his duty, with becoming modesty, to keep his fellow-practitioners informed of advances in his own line, being careful to avoid a controversial attitude, as though there were some competitive element in the various treatments or methods of diagnosis.

will allow him with marvelous complaisance to accept a check each month as a *pro rata* of the work he has sent to an X-ray laboratory. How can these physicians themselves have any respect for a branch of medical work which indulges in such practices, even though they are receiving gratuities from them?

This disgrace will be abated only when our medical laws are improved, and when the radiologic profession, by its own improved practices, which I shall mention later in the paper, has shown that it can lift the specialty to a higher plane.

Closely allied to this subject is the one which deals with our relation to the radiologic technician. There is none of us but will gladly admit the great dependence we place on an efficient technical assistant. With the increasing facilities for detail work, and the resultant widening usefulness of radiologic diagnosis, the demand for expert technical service is daily becoming greater.

To-day the increasing importance of the highly trained technical assistant in busy radiologic departments may cause undue stress to be laid on this purely technical phase of the work, and, too, we are prone to let patients pass through our offices or departments, seeing only the technical assistants and the bookkeeper, never having a single contact with the professional side of the organization. Little wonder, then, that the public comes to view the layman's services as constituting the entire performance, nor is it entirely unnatural that the assistants, particularly the male ones, may at times, without intention, begin to assume an importance which threatens to be somewhat top-heavy, to say the least.

I was impressed with this fact, and not a little shocked, very recently to read in one of our leading radiologic journals an advertisement which was worded, "Associate wanted [Mind you!] Experienced technician desires to associate with physician in-

terested in X-ray and light therapy. Must be young, progressive, and open-minded."

It reminded me of some recent interviews with prospective domestic help. Before I had a chance to ascertain if they could cook well enough for me to employ them, they were investigating my qualifications as an employer.

Our own history of development may have a certain bearing on this situation. It is a fact that some of our most cherished names in radiologic history are those of men who in their early years were not medical graduates. Such men as the beloved Caldwell and Walter Dodd, as well as some living and active to-day, began as laymen. But all the more significant is the fact that they eventually realized that, without a medical education, even they were not giving a service worthy of its dignity to their chosen work.

The production of a technically beautiful roentgen film of a difficult portion of the body is a work of skill and of art. It is an honor to the man or woman who produces it, and deserving of all praise, often more than it receives. However, just as those illustrious pioneers in radiology who started as laymen found that their usefulness had very distinct limits until they had rounded out their medical education, just so does the lay radiographer of to-day meet a very sharply marked boundary at the point at which his function ends and that of the professional service of the roentgenologist begins. Fortunate is that technician who realizes this fact and complies with its exactations, for he has in store for him years of happy association with the medical profession with the enjoyment of mutual confidence and appreciation. He can gain nothing but distrust and disturbed and unhappy relations by any other attitude.

This Society has done a distinct service in the fostering of the Registry of Radiological Technicians, an organization that has a code of conduct which, if adhered to, will

go far toward maintaining the attitude of the roentgenologist and technician toward each other as a happy one

Admitting the importance of all these external influences, there is to my mind a problem much nearer home which demands solution, the close and conscientious attention to which will go further than any one thing toward enhancing the value of the radiologist in his medical community, and bringing him to that position of recognition which the importance of his specialty deserves. Our great fault, I believe, is the position so many of us have assumed of isolating ourselves from the clinical practice of medicine. We have burned up the roads between various branch offices and hospitals on film-reading expeditions. We have seen little of our patients, except when fluoroscopy was needed, and have neglected even then to take a personal interest in the clinical side of the case. We have failed to discuss cases fully, as we should have done, with the referring physician. We have not acquainted ourselves with his problems in the particular case in which he is seeking our help. How can we expect him to consider us as consultants if we do not even see his patient, or ask for the history and clinical and other laboratory data?

Most emphatically do I assert that until we institute a very distinct reform in this practice radiology will never be considered much more than a mere incidental influence in the diagnosis and treatment of disease. Unless we renew within ourselves the realization that we are practising medicine, first, last, and all the time, we can never expect the profession or the public to recognize us as standing shoulder to shoulder in the front rank with the specializing internist, surgeon, laryngologist, and the other specialties.

In a recent issue of *RADIOLOGY* one of our members wrote a very fitting tribute to a confrère who had died in an Eastern city. Most pointed was the remark, "He was a physician practising radiology." How aptly

put! What a stinging rebuke to those of us who have fallen so far short of the full measure of our usefulness, and whose knowledge of the patient entrusted to us is too often confined to a few square inches of celluloid!

In the progress of our specialty toward maturity we shall find that more frequently the patients are seeking the services of the radiologist first hand. I am sure most of us are experiencing this already. Heretofore we have had all but a very small portion of our work referred by other physicians, and we have been largely depending on the patronage of a profession which is notoriously whimsical. (It is permissible to say this since we include ourselves with the rest.)

I believe that the opinion expressed by Dr Groover in a recent editorial is correct. We shall find with increasing frequency that patients will seek radiologic advice and service on their own initiative or will suggest it to their attending physicians. It will consequently follow that the radiologist will himself become a referring physician. He will be directing patients to other specialists for certain services. His stock will rise noticeably then. It only remains necessary that the radiologist keep himself *clinically alive*, and maintain his touch with the progress of medicine in other lines. With strict adherence to the ethical principles, with which we are all conversant, he can pursue this course with perfect justice to his referring clientèle, and grow in respect and usefulness. He must prepare himself to discuss intelligently, in staff and medical society meetings, all cases that he has contacted or that concern his work, and by "intelligently" I mean with the ability to realize the clinical significance of the case. It is his duty, with becoming modesty, to keep his fellow-practitioners informed of advances in his own line, being careful to avoid a controversial attitude, as though there were some competitive element in the various treatments or methods of diagnosis.

I think we have drawn a little fire of antagonism from certain quarters by an attitude, which we are sure is well founded, on such subjects as the therapy of toxic goiter and certain malignancies. We should be careful in this matter.

Let no one think, who may read this paper, that I am in any way complaining of monetary loss caused by these unfriendly influences. I believe there will always be enough for the qualified radiologist to do so that he will be provided with a decent living. My arguments are purely from the standpoint of the dignity of our profession, for, after all, our richest pay is the joy of

service—through a medium in which we can justly take pride.

All in all, the specialty of radiology appears to me to have a most alluring future in its ability to serve the sick, both directly and through pleasant contacts with the profession. This will be chiefly, not through worrying about medical laws or the numerous pestilences that harass us in the form of quackery and dishonesty, but through the broadening of our medical lives into the full scope of usefulness they should possess, that is, by being "physicians practising radiology."

CHARLES M. RICHARDS, M.D.

COMMUNICATIONS

RESOLUTION

At the Annual Meeting of the Society, held in St. Louis, Nov. 30-Dec. 4, 1932, the following Resolution was adopted:

Resolved, That the Executive Committee of the Radiological Society of North America is authorized and is hereby specifically instructed to employ accountants and clerical help and to take any measures which, in its judgment, are necessary or desirable to put the financial affairs of the Society on a sound business basis, and to enable this Committee to render complete and exact financial statements of the cost of the Society to its members, and of the cost of its Journal to the Chemical Foundation, and to make any further agreement with the Chemical Foundation which, in the best judgment of the members of the Committee, are proper and will tend to enlist its further support.

The adjustment covered by this Resolution is still going forward, necessitating

much labor by members of the Executive Committee and especially our President, Francis Carter Wood, M.D., and our Secretary-Treasurer, Donald S. Childs, M.D. It is hoped that their efforts may result in arrangements whereby the Journal may continue to be a source of satisfaction to its readers.

DISCONTINUANCE OF JOINT SUBSCRIPTION

It has been decided to discontinue the joint subscription rate for *The American Journal of Cancer* and *RADIOLOGY*, as announced in *RADIOLOGY*, December, 1930, XV, 700. The subscription rate of *The American Journal of Cancer* is \$5.00 in the United States, \$5.50 in all other countries. The subscription rate of *RADIOLOGY* is \$6.00 in the United States, Canadian and foreign postage \$1.00 additional.

It is hoped that all physicians interested in radiology are already or will become subscribers to both journals.

SUB-COMMITTEE ON RADIOLOGY

Dr Leopold Jaches, of New York, has been appointed a member of the Sub-committee on Radiology to the International Hospital Association for the study of the care of the patients in hospitals. This honor was conferred upon him by Dr Hans Holfelder. The principal questions to be considered are the following:

- 1 Specialization of the entire field of roentgen diagnosis and radium therapy, its establishment as an independent specialty and its right to independent quarters in the hospital
- 2 Centralization or de-centralization
- 3 Does the radiological division require its own bed units?
- 4 Arrangement and disposition of space and technical adjustment
- 5 Scope and limitations of radium therapy in the hospital and conditions of its application

Dr Jaches is to represent the member from the United States. There are twelve countries in all, each sending one representative.

AN APPRECIATION

Under the assistant-editorship of S W Donaldson, M D, of Ann Arbor, Michigan, *The Journal of Phi Rho Sigma* has issued a Roentgenological Number (January, 1932). It contains papers by B R Kirklin, M D ("Graduate Training in Roentgenology"), L R Sante, M D ("The Economic Phase of Radiological Practice"), James D Bruce, M D ("Post-graduate Teaching of Roentgenology"), Clyde K Hasley, M D ("X-ray Therapy"), and S W Donaldson, M D ("Choosing Roentgenology as a Specialty"). There are splendid editorial comments by Albert Soiland, M D, Jonathan Forman, M D, Walter M Simpson, M D, Norman MacNeill, M D, and S W Donaldson, M D. The *Journal* has a circulation of some 6,000

among medical men and, besides the articles enumerated, contains much material of interest to members of Phi Rho Sigma and Chi Zeta Chi. The editors are to be congratulated upon a publication of real value.

RADIOLOGICAL SECTION OF THE LOS ANGELES COUNTY MEDICAL ASSOCIATION

At a meeting of the Radiological Section of the Los Angeles County Medical Association, held December 16, 1931, the following officers were elected for 1932: President, W E Costolow, M D; Vice-president, Karl Bonoff, M D; Secretary, D R MacColl, M D; Councillor, Kenneth Davis, M D; Treasurer, Henry Snure, M D.

DEATH OF MR WILLIAM H DODGE

It is with regret that we have learned of the death of Mr Dodge, on February 1. He has been known to many roentgenologists throughout the country as one of the best X-ray technicians, who took pride in producing fine roentgenograms and in teaching others to do the same. He numbered among his friends leading radiologists and apparatus builders, who had respect for Mr Dodge's ability and maintenance of high standards in his chosen field.

THE RADIOLOGICAL REVIEW
RADIUM NUMBER

The March, 1932, issue of *The Radiological Review* will be entirely devoted to Radium Therapy, this being the fifth annual "Radium Number." Short original articles on clinical radium therapy that will be of interest to the general profession are solicited. All contributions should be in the hands of the Editor (P O Box No 152, Quincy, Illinois) not later than February 20, 1932.

BOOK REVIEWS

THEORY AND PRACTICE OF TELECURIERTHERAPY By MAX CHEVAL and A-P DUSTIN Pages, 240, illustrations, 76 Masson et Cie, Paris, 1931 Price, 34 francs¹

In this work of clinical radiologic and biologic research will be found most valuable technical instruction, as the authors' main purpose was to relieve radiotherapists seeking information in this field of the inevitable initial uncertainties.

This volume, which sums up a three-year experiment along clinical and therapeutic lines, consists of three divisions.

The first part is devoted to the organization of a telecurietherapy station and the technic of treatment.

Then comes an investigation of the biologic action of telecurietherapy on both general conditions and on tissues or various malignant cells.

In conclusion, the authors deal with clinical considerations referring to indications of technic in different cases of neoplasms. They report a number of observations, to which they add the enumeration and results of all the cases treated in three years.

Translation by HENRY BAYON, M D

PHOTOBIOLOGIE By LUDWIG PINCUSSEN, M D, Phil Direktor der Biolog-Chemischen Abteilung am Stadt, Krankenhaus am Urban, Berlin Pages, 543, illustrations, 101 Published by Georg Thieme, Leipzig, Germany, 1930 Price, 36 marks

logical results obtained by various investigators, both in pure research and from the standpoint of their application to disease conditions as well as the maintenance of normalcy, are presented in a systematic and comprehensive form. The volume will be of particular value to those interested in ultraviolet therapy.

The first portion of the volume deals with radiation and the laws of radiation, absorption spectra, fluorescence, the qualitative and quantitative determinations of radiant energy in sunlight, arc and spark spectra, photo-electric effects and physico-chemical changes produced by radiation. Nearly seventy pages are devoted to chemical effects such as isomerism, polymerization, oxidation, and reduction phenomena and photosynthesis.

The second part (over 300 pages) of the volume deals almost entirely with the biological effects of radiant energy, chiefly ultra-violet. The absorption of light by living organisms, the regulation of this absorption and the development of pigment, the influence of light on the growth of cells, micro-organisms, plants and animals, the effects on animal and plant metabolism, the influence of light on the nervous system, internal secretions, the blood, the skin and body temperatures, and the relations of light to the organ of sight are among the important topics which are considered and dealt with adequately but not in detail.

The text is replete with citations and adequate references are given. For instance, over 300 references constitute the bibliography of the chapter on the chemical effects of light. These references are to both foreign and American investigators and are brought down to the year 1930. The bibliography, in and of itself, is extremely valuable, as well as indicating the thorough acquaintance of the author with the field of photobiology. The book can be recommended to those who are desirous of possessing an up-to-date treatise on this subject.

This is an excellent compilation of facts and theories concerning the action of radiant energy (ultra-violet, visible and near infra-red) on animal and plant tissues. The fundamental physical principles and the bio-

SURGICAL PATHOLOGY OF THE DISEASES OF BONES By ARTHUR E HERTZLER, M D, Professor of Surgery, University of Kansas, and Surgeon to the Agnes Hertzler Memorial Hospital, Halstead, Kansas Pages, 272, with 211 illustrations Published by J B Lippincott Company, Philadelphia, 1931

This volume is one of a series of surgical-pathological monographs, which the author has written or proposes to write. The publication is excellently illustrated with ample and clear-cut roentgen-ray reproductions and photomicrographs. The descriptions of the ordinary affections of the bones are well written and clear. For the use of the surgeon it is to be highly commended. The author makes no claim that it is for more advanced study of the diseases of bone. His claim that there was a need for a pathology of diseases of bones is true. He has filled this need for many.

The subject of bone tumors is well discussed. While the author does not adhere strictly to the classification of the Registry, his reasons for this are well taken. This particularly difficult subject leaves much to be desired in the literature, and the author has assembled the available knowledge in a comprehensive way.

The discussion of joint affections is not so satisfactory from the standpoint of one interested in these conditions. However, the book is on diseases of bones and it may have been the author's intention to pass over the subject of joints. In the discussion of tuberculosis, however, the statement that "there is even grave doubt whether or not the disease is ever primary in the synovial membrane," might lead to a considerable amount of discussion as the more modern conception of joint tuberculosis certainly does not subscribe to that statement.

As a guide to the pathology of the more common affections of bone we can recommend this volume.

EXPLORATION RADILOGIQUE DE L'APPAREIL RESPIRATOIRE By EMILE SERGENT, Professeur à la Faculté de Médecine de Paris, Member de l'Academie de Médecine, FRANCIS BORDET, Ancien Chef de Clinique de la Faculté de Médecine de Paris, and HENRI DURAND, Chef du laboratoire de la Clinique de la Charité. With the technical collaboration of J COUVREUX, Chef du laboratoire de Radiologie de la Clinique de la Charité. Published by Masson et Cie, Paris, 1931. Two volumes, 465 pages, with 639 illustrations including 580 radiographs. Price, 350 francs.

various clinical signs, symptoms, laboratory and autopsy findings and thus place the interpretation of the roentgenologic changes in respiratory conditions on a more logical foundation. While this work is purported to be an iconographic atlas, such a description does not do justice to the accompanying text in which the multiplicity of intrathoracic shadows has been analyzed in an amazingly practical manner. The text is also replete with such information as is accumulated only from years of experience.

The first part (33 pages) is concerned with the technic of the roentgenologic examination. It is quite brief, but covers the practical essentials. The novice will wish that this subject had been considered in more detail, but, as the book is written primarily by clinicians, from their viewpoint

This excellent pictorial atlas of the chest has been prepared by eminent clinicians of wide experience. It is their purpose to correlate the roentgenologic findings with the

this omission of technical roentgenologic details may be pardoned

The authors have analyzed the roentgenologic findings in a rather unique fashion, considering first the normal chest, later the fundamental pathologic changes, and lastly the more complex pathologic changes. The detailed description of the fundamental pathologic changes is most excellent, and the photographs of pathologic specimens add

much to the value of the many excellent roentgenograms. The section devoted to bronchial affections is unusually comprehensive and is supplemented by many lipiodol studies. The cuts, typography, and binding are of superlative quality.

This is undoubtedly one of the finest books on the subject available, and even the experienced radiologist will find it of great value.

King George Knights Dr Henry S Wellcome—Many friends and associates of Dr Henry S Wellcome in the United States will be gratified to learn that knighthood was conferred on him in King George's New Year honor list in recognition of his generous support of medical research. He is a native of Wisconsin and became a British subject by naturalization. He was graduated at the Philadelphia College of Pharmacy and Science. He is a Director of the Gorgas Memorial Institute of Tropical and Preventive Medicine Washington, which operates scientific laboratories at Panama for research work touching causes and prevention of tropical diseases.

In connection with the monumental sanitary work of General Gorgas in Panama, it is recalled that at one time an attempt was made

to cut down appropriations which would have seriously handicapped the progress of the work. The Secretary of War, the Hon. J. M. Dickinson, who knew of Dr. Wellcome's experience and interest in tropical research, asked him, while in Washington in 1910, to visit Panama and make a thorough, detailed inspection of the conditions and methods of operation in all sections of the Canal Zone and to submit an unbiased report based on his personal observations.

Dr. Wellcome is a life member of the American Pharmaceutical Association and has taken an active interest in its scientific work since the beginning of his membership in 1875. At the last annual meeting of the Association held in Miami, Florida, during July, 1931, he was elected Honorary President.

Dr. Wellcome has received world-wide recognition for his great service to science and medicine, for his interest in missionary enterprises, and for his personal work in medical research, the history of medicine, and for his archaeological and ethnological explorations and studies.

THE ABDOMEN

Methods of Orientation in the Diagnosis of an Acute Abdomen Alejandro I Pavlovsky Rev Med Cubana, October, 1931, XLII, 1228-1234

This article is meant particularly for the instruction of the practitioner who, in order to make a responsible diagnosis, is forced to depend almost entirely on the history and physical examination of the patient. It is an article of bedside diagnosis when the laboratory is either not available or the urgency of the case is such that there is no time for such examination.

The author goes into minute details of history-taking and does a thorough physical examination. He leaves all laboratory examinations as a last resort. It does not mean that he does not believe in laboratory examinations, but he wishes to impress the practitioner with the fact that a diagnosis may be made in the absence of laboratory tests.

The reason for which this author leaves X-ray examinations to the last is that it is difficult to obtain reliable plates in urgent cases. He does not leave out or overlook the importance of the X-ray. On the contrary, he emphasizes the value of this examination, when possible to make it. He cites such examples as cases of perforated peptic ulcers in which the presence of air in the peritoneal cavity will clinch the diagnosis.

A volvulus of the sigmoid colon and an ovarian cyst with a twisted pedicle give similar physical findings. By the use of a barium enema and the fluoroscope or X-ray films, a differentiation can be made. When the colon is filled the volvulus will show, but if it is an ovarian cyst, the colon will not show any irregularity but will be displaced upward and laterally. Thus, the author concludes by making the statement that X-ray examination is of inestimable value in many cases.

JOSEPH MALDONADO, M.D.

Exploration of the Abdomen by X-rays C W Prowd Canadian Med Assn Jour, October, 1931, XXV, 444-446

This is the ninth in the series of articles be-

ing published in the *Canadian Medical Association Journal*, contributed by the Canadian Radiological Society, and dealing with physiotherapy in all its aspects. In this paper, the author keeps in mind the object of the series to educate the general profession, and sums up very concisely the progress which abdominal diagnosis has made since the advent of the X-ray.

A generation ago there was no X-ray. Today it is the greatest single factor as a diagnostic aid in all abdominal conditions. Not one but all the abdominal organs may be visualized either directly or indirectly. Exploration by X-rays forestalls examination by all other methods. No other means affords the same accuracy and certainty. It may even exceed inspection by the surgeon. Pre-pathologic conditions and disease in its incipiency are detected, as in malfunction of the gall bladder, stomach, and bowels. It has an important bearing on early diagnosis, and will loom large as a factor in preventive medicine. There are many unsolved problems to be attacked, but the accomplishment of the past gives promise for the future. We know the relative frequency and location of esophageal lesions, benign or organic. Cardiospasm and cancer, especially of the cardiac end of the stomach, are confusing, but the borderline case vanishes as the examiner becomes more expert.

We have learned that the large stomach, with so-called dilatation and prolapse, is peculiar to and characteristic of the asthenic type, and that it means no more than a long nose or a big foot, provided that it functions properly. Not more than 15 per cent of all cases with stomach symptoms have organic lesions of the stomach or duodenum. Duodenal ulcer is five times as frequent as gastric ulcer, and gastric cancer twice as frequent as gastric ulcer. Two-thirds of all gastro-duodenal lesions are duodenal ulcers, while cancer of the duodenum is the rarest of all lesions.

The X-ray has questioned or confirmed the accuracy of many statistics. Thousands of cases give decided values. The prominence of certain diseases has been lost. The liver and colon are often proved double offenders, and

the innocent appendix relegated to a minor part

The liver and gall bladder are the frequent sites of disease Opaque dye, administered orally or intravenously, has been of striking value in estimating liver and gall-bladder function and disease Gall-bladder disease is the most frequent organic cause of dyspepsia, pain, and gastric symptoms It is the source of trouble in about 25 per cent of all cases, and represents a higher percentage than the combined lesions, organic and functional, of the stomach and duodenum The frequency of gall-bladder and colon disorders is more and more emphasized They are closely inter-dependent A constipated colon and a constipated gall bladder constitute dual and parallel conditions

The secrets of the small and large gut are still largely unexplored or misinterpreted No field offers more for research than the twenty-five feet of the small and large intestine They still hold many secrets and remain the dark continent of the abdomen, with their intricate uncharted coast lines

Roentgen data are invaluable to the urologist Definite data are given by combined pyelographic and roentgenographic study The new method of intravenous pyelography gives promise of much usefulness, especially as an aid to the regular pyelographic examination

The female pelvic organs are examined by lipiodol, with good diagnostic results

There still remain the spleen, pancreas, blood-vascular and muscle tissues to present problems for the future.

No field is too obscure, no effort too great, no problem too difficult for the realm of the X-ray Never has sacrifice been so great as in this new science There is need to-day of greater precaution and care, recreation and limited hours The future is big with promise, the past replete with accomplishment, the present a high hour of endeavor Men and material, medicine and physics, have worked together to solve and to throw light on the great unknown The closed abdomen is revealed in the new light of twentieth century science

(Abstractor's Note.—The abstractor reviews, with pleasure, such an article as this

one, contributed by Prowd, and hopes that this somewhat extended abstract will stimulate more of our brethren to extend their efforts in the education of the general profession in the scope and accomplishments of our specialty)

APPARATUS

A New Instrument for Measuring the Hardness of Roentgen Rays, Called "Durometer" S Strauss and H-Th Meyer Strahlentherapie, Oct 3, 1931, XLII, 343-350

The authors describe an instrument, designed by Schreus, which is based on the penetrometer of Christen It permits the determination of the half value layer of roentgen rays by means of a fluoroscopic screen and a calibrated wedge The percentage of error is said to be ± 5 per cent For details of the construction, see the original article

ERNST A POHLE, M D, Ph D

Purification of Radon J Bannon. Journal of Cancer Research Committee of University of Sydney, August, 1931, III, 86-89

The author has designed a simple, liquid-air, radon-purifying apparatus which is quick in action, gives very satisfactory purifications, and is safer than many other types It has been in use for fifteen months When radon is not being drawn off, mercury protects the stop-cock leading from the radium container so that the grease on the cock is not decomposed, frequent greasing being then unnecessary Although the design of the apparatus differs widely from the conventional pattern which was abandoned in favor of the present design, the methods employed are similar

For preparations of the order of 300 mc., a concentration of 12 mc of radon per cubic millimeter at a pressure of 25 cm of mercury may be obtained Thirty Muir seeds can be made in twelve minutes For details reference must be made to the original paper

J G STEPHENS, M D

Apparatus for the Sterile Catheterization

of the Bronchi Armando Dei Rossi
Minerva Med, Oct 6, 1930, XXI, 481, 482

The author has developed an aseptic sound to extract specimens of the tracheo-bronchial flora, free from the bacteria usually present in the upper part of the respiratory tract. It consists of a curved tube having at one end two small jaws which can be opened or closed at will from the outside. A catheter is introduced into it, and the whole instrument, with its jaws closed, is lowered into the trachea; from there, by opening the jaws, the catheter may be pushed into one of the large bronchi.

The instrument has special importance also in bronchography, because it permits direct injection of opaque media in the lower parts of the bronchial ramifications. An X-ray photograph shows well how near the end of the catheter is to the diaphragm. The author has found the instrument perfectly satisfactory in the examination of 150 patients.

L MARINELLI

A Simple Uroselectan Outfit O LeGrand Suggett Urol and Cutan Rev, October, 1931, XXXV, 666

The author has devised for the administration of uroselectan a simple gravity apparatus which enables one to mix, sterilize, and administer the drug with a single container. A 125 c c Ehrlemeyer flask, fitted with a rubber stopper penetrated by two pieces of glass tubing, is employed. One piece of the tubing is flush with the inside of the stopper, but protrudes an inch from the outside for attachment of the rubber tubing. The other piece is flush with the outside but long enough to come within half an inch of the top of the flask to permit the entrance of air. Three feet of tubing, with an adapter to fit a Schreiber or other intravenous needle, and a short section of glass tubing for a window near the distal end completes the apparatus. A clamp was found of great value by the author, for attaching the flask to either a horizontal or a vertical support.

J N ANE, M D

THE APPENDIX (DIAGNOSIS)

Roentgenologic Signs of Appendicitic Ab-

scusses Sigfrid Arnell Acta Radiologica, 1931, XII, 359-368

The author discusses the roentgen signs of appendicitis and especially those of appendiceal abscess. He feels that this phase of diagnosis has been neglected and deserves greater use in the examination of doubtful abdominal cases. No definitely direct roentgen findings are seen in uncomplicated appendicitis, but roentgen examination with or without the use of contrast medium is frequently helpful in showing lateral appendiceal abscess. He mentions the roentgen signs as described by Laurill and Westerborn (*Surg, Gynec and Obst*, 1931, LII, 804), these consisting of shadow of inflammatory process, haziness of renal contours, gas in abscess, appendiceal calculi, and contrast filling of fistulous tract and cavity.

M J GEYMAN, M.D.

Intussusception of the Appendix E W Mitchell Canadian Med Assn Jour, August, 1931, XXV, 194-196

This is a case report of a patient, Mrs P., married, aged 28, who was admitted to the Toronto General Hospital on March 28, 1931. There was no history of previous illness. Four days before admittance, at 6 p m, she began to have dull epigastric pain. During the night the pain became more severe, spasmodic, and colicky in nature, and was referred to the region of the umbilicus. The paroxysms of pain occurred about every two hours, were short in duration, and agonizing. After each paroxysm of pain she felt absolutely well. There was no vomiting and she had a normal bowel movement.

She continued at her occupation for three days following the onset. During this period the paroxysms of pain continued, were definitely colicky, referred across the abdomen at the level of the umbilicus, and recurred about every two hours.

On examination the patient did not appear ill. The abdomen was scaphoid, and there was no visible peristalsis or mass. There was tenderness, without rigidity, on the right side from McBurney's point to the costal margin. The rectal examination was negative and the temperature and pulse were normal. The

white blood count was 7,600 and the urinalysis was negative for sugar and albumin, microscopically, there were a few pus cells

She was admitted to the hospital, and a diagnosis of appendicitis was made. At operation the appendix could not be visualized, but at the junction of the *taenia coli* a depression could be seen into which the meso-appendix was traced. The appendix was felt as an elongated mass within the cecum. An attempt to reduce the intussuscepted appendix failed. The cecum was opened through and parallel to one of the longitudinal bands, the appendix was clamped at the base and removed. The opening in the cecum was closed and the wound closed in layers without drainage. The convalescence was uneventful.

A study of the literature shows that intussusception of the appendix is rare. At Mount Sinai Hospital, New York, in 5,000 operations for appendicitis, one case of intussusception of the appendix occurred, as reported by Moschkowitz. The author has been able to collect from the literature 70 cases, a few of which were probably not true intussusception.

The important points in the clinical history and examination are the colicky pain, with definite remissions, the absence of rigidity, mass, and vomiting. The early recognition and treatment would save the more serious complications of massive intussusception of the bowel.

L J CARTER, M D

Diagnostic Considerations Regarding Appendicitis, Chronic in Origin, and Gastric and Intestinal Manifestations M Trincas L'Ateneo Parmense (Suppl), 1931, III, 283-304

On the basis of 150 cases, which he studied in detail clinically and radiologically, the author discusses the disputed question of the reflex action of appendicitis of chronic origin. The results of his investigations are summed up in the form of percentages of the total number of cases as follows:

Classic cases of chronic origin, with pain in the appendicular site or located anomalously, and with phlogistic complications of various nature, 132, or 88 per cent

Forms prevailingly gastric, twelve, or 8 percent. These were equally divided between hypersthenic and hyposthenic.

Forms prevailingly intestinal, six, or 4 percent. Of these, forms with prandial diarrhea numbered two, with postprandial diarrhea three, and with spastic occlusion one.

W W WHITELOCK, Ph D

THE BLADDER

Leiomyoma of the Bladder With a Report of a Case and a Review of the Literature Herman L Kretschmer *Jour Urol*, October, 1931, XXVI, 575-589

A case of leiomyoma of the bladder in a young girl of nineteen is reported. The literature on this type of bladder tumor has been very well reviewed and is incorporated in the article. Frequency, etiology, age, sex, symptoms, diagnosis, treatment, and prognosis are considered. An extensive bibliography accompanies the paper. A cystogram is reproduced which demonstrates bilateral filling defects occupied by the tumor substance. Illustrations of the surgical specimen and photomicrographs of the author's case are also included.

DAVIS H PARDOLL, M D

A Case of Extroversion of the Urinary Bladder J S McEachern *Canadian Med Assn Jour*, September, 1931, XXV, 324

The mother of a female infant, aged 12 weeks, noticed a mass protruding from the vulva, while the child was crying hard. At 4 P M, the physician reduced the mass and sent the patient in for an examination. The mass recurred after a fit of crying while in the hospital. It was again reduced but the condition not diagnosed. Under an anesthetic the child was examined and the vagina and cervix appeared normal. The anesthetic was stopped and the child began to vomit. Slowly the urethral orifice was seen to dilate, and a mass was suddenly extruded from it. This mass quickly became a deep bluish black. Pressure between the finger and thumb flattened it out. Lifting it forward, the orifice of one ureter could be seen, the extroversion was easily reduced. The child was kept in bed with the

foot of the bed elevated for about a month There was no recurrence of the trouble Nine years later the patient was examined and nothing abnormal was found

The parents reported that for the first two years the child had no urinary control From that time on there was improvement in control and for the last three or four years it has been normal

L J CARTER, M D

BLOOD CHANGES

Influence of Roentgen Irradiation on the Sodium Content of the Blood Serum Karl Adler Strahlentherapie, Oct 24, 1931, XLII, 584-590

The influence of roentgen irradiation on the sodium content of blood serum was studied in rabbits and in patients In rabbits, which had received a surface dose of 1,000 r, the sodium content of the blood serum was decreased by from 6.54 to 15.4 per cent of the initial value Patients who were treated with the usual roentgen and radium doses showed no changes in the sodium content of the blood

ERNST A POHLE, M D, Ph D

The Influence of Roentgen Rays on the Alkali Reserve of the Blood Kurt Kading Strahlentherapie, Oct 24, 1931, XLII, 571-583

The alkali reserve of the blood is usually constant, but it can be influenced by a number of factors, for instance, disease, anesthesia, work, and irradiation The values usually move towards the acid side, while alkalosis was not observed by the author He found that in malignant tumors of the genital organs the alkali reserve is very low Following roentgen irradiation it increases in some and decreases in other patients Since only a small number of cases were studied, no definite conclusions could so far be drawn

ERNST A POHLE, M D, Ph D

BONE (DIAGNOSIS)

Fracture of the Iliac Bone, with Sinking of the Acetabulum and Intrapelvic Luxation

of the Femoral Head Alberto Fernández Saralegui La Semana Méd, Sept. 10, 1931, XXXVIII, 799-804

The author presents this case because of its rarity A man, 40 years of age, was struck by an automobile which was going at a low rate of speed The blow caused him to stagger forward, leaving the right leg in flexion and the left leg in extension While he was in this posture, the bumper of the car struck him on the external part of the left leg He immediately felt pain as if a bone had been broken His left leg remained in flexion and thus he was carried to the hospital

Attempts to correct the vicious position resulted in a reduction of the flexion On examination, the left leg was found in flexion, adduction, and internal rotation, with the left foot resting on the internal aspect of the right one and the left knee resting against the internal aspect of the right one In the left hip, there was noticed a flattening due to total disappearance of the prominence produced by the greater trochanter Measurements revealed a shortening of 5 cm as compared to the right extremity The Nélaton-Roser line was found in accordance with this shortening and so was the Shoemacker line The deformity of Bryant's triangle was found in relation to the displacement of the greater trochanter Rectal examination revealed the new position of the femoral head, with the piece of bone torn from the acetabulum in front of the femoral head Radiographs showed intrapelvic luxation of the femoral head, measurements showing that it had penetrated so deeply as to reduce the size of the pelvic cavity about one-third There was fracture of the antero-lateral segment of the iliac bone and also fracture of the lesser trochanter

The treatment was instant reduction, massage for four weeks, and walking exercises after eight weeks The results were good for that type of fracture

N G GONZALEZ, M D

BONE (THERAPY)

Avulsion of the Lesser Trochanter of the

Femur J S McEachern and H N Jennings Canadian Med Assn Jour, October, 1931, XXV, 449, 450

A healthy athletic boy, 16 years of age, was running to catch a street car. He slipped on some ice, caught his right foot in a rut, and saved himself from falling by a violent backward jerk of the body. There was immediately severe sharp pain in the right groin and the adjacent part of the thigh. After a few minutes he was able to walk to the street car, holding the right leg and hip stiff, and sliding the right foot along the ground.

X-ray examination showed the lesser trochanter of the right femur to be torn loose at the epiphyseal line and drawn upward and forward about 3 centimeters. The patient was put to bed and the right leg suspended in a bent Thomas splint, hung from a Balkan frame, with the hip flexed to 100 degrees. After the first day there was no pain. After four weeks in this position the leg was lowered by degrees, and in another week the patient was allowed to be up, with crutches. A second film taken at this time showed the epiphysis drawn back into partial contact with the diaphysis, about 2 cm from its proper position, and good bony union had apparently occurred.

The authors call attention to the fact that avulsion of the trochanter is a rare injury. They have been able to bring the number of reported cases up to forty-eight (*Note*—The abstractor has one case which he has not reported.)

Common symptoms are pain in the groin, inability to flex the thigh, and, usually, inability to walk.

L J CARTER, M D

BONE DISEASES (DIAGNOSIS)

Unusual Forms of Familial Osteochondrolystrophy T Dale Acta Radiologica, 1931, XII, 337-358

The author reports three cases of an unusual familial skeletal disease. They differ from chondrolystrophy in that the extremities are of normal length while the trunk is

abnormally short. The disproportion becomes more pronounced as age increases. The most marked osseous abnormalities occur in the spine and consist of defects in ossification, resulting in various degrees of kyphosis and scoliosis.

Marked irregularity of the upper femoral epiphysis occurred in all three cases. Similar changes were also seen in the proximal epiphyses of the humerus in two of the cases, and of the distal forearm epiphyses in the first and third cases. The author believes the etiology to be on an endocrine basis.

M J GEYMAN, M D

Diffuse Bone Endothelioma (Ewing) Julio Diez La Prensa Méd, Aug 30, 1931, XVIII, 396-414

The author presents here a good treatise on this subject, the purpose of which is to prove that such a tumor does exist. He follows the ideas of Ewing, Kolodny, and Connor. He gives a good review of the literature and presents photomicrographs and radiographs of the condition. Great praise is given to American investigators.

N G GONZALEZ, M D

Chronic Tuberculous Hygroma of the Deep Trochanteric Bursa Francesco Satta La Radiologia Medica, November, 1930, XVII, 1251

This article is a complete report of a patient suffering from hygroma of the trochanteric bursa. Radiologic examination disclosed not only the size of an extremely distended bursa, but also the diffusion of its contents to the surrounding tissues through the weaker points of its membrane.

L MARINELLI

Femoral Condylitis Report of Cases Merrill Coleman Mensor Calif and West Med, August, 1931, XXXV, 121, 122

The author reports two cases which he has designated as femoral condylitis. The history is that of sharp boring pains on the outer side of the knee. X-ray examination shows a small defect over the external condyle about two

millimeters in diameter, with a small calcified mass about the same size adjacent to it in the soft tissue. This has been diagnosed as a small avulsion fracture and as a chip fracture with periosteal tear. As far as history by repeated interrogation can determine, trauma is definitely excluded.

The X-ray findings of an apparent fracture are not explained. In this condition are found all the signs of acute inflammation. Because of the conflicting reports of the inflammatory signs and the X-ray appearance, the relation of this condition to industrial medicine is important, due to a medico-legal aspect.

FRANCIS B SHELDON, M D

The Diagnosis and Treatment of Acute Osteomyelitis in Children Grover C Penberthy Jour Michigan St Med Soc, June, 1931, XXX, 424-428

The X-ray findings in the acute stage are of little value, at the end of four or five days, irregularities and changes in density may be made out. The history and clinical findings should be given to the roentgenologist to assist in the interpretation of the X-ray appearances. The best possible technic of obtaining bone detail must be used, and the examination should include the opposite limb for comparison. The age of the patient and the duration of the disease are factors which enter into the technic.

W W WATKINS M D

Leprotic or Tuberculous Arthritis? Francesco Satta La Radiologia Medica, December, 1930, XVII, 1395-1398

The author has found an osteo-arthritis process under the astragalus, with phenomena of rarefaction and reabsorption on one side and osteoperiostitis on the other. The patient was affected with lepra tuberosa florida, although the general appearance of the lesion suggested that it was of tuberculous nature.

L MARINELLI

Malignant Osteoclastoma J W Orr Jour Path and Bacteriol, March, 1931, XXXIV, 265, 266

A case is reported in which sections from

the lungs of a museum specimen showed metastatic tumor nodules containing numerous giant cells of the osteoclastic type.

Subsequent investigation elicited that the patient had had the right leg amputated for a growth of the lower end of the femur. The microscopic diagnosis at the time of amputation was "myeloid sarcoma".

Note "Myeloid sarcoma" or "osteoclastoma" are the terms used in England for what in America is known as benign giant-cell tumor of the bone.

E C VOGT, M D

Kohler's Disease in the Third Metatarsal Bone Giuseppe Grado Archivio di Radiologia, May-June, 1931, VII, 557-569

According to the author, in the statistical review of Cahen-Brach, based on sixty-three cases in the literature, in only five was there involvement of the third metatarsal. His case, a boy of ten, had a characteristic lesion in the third metatarsal and the base of the phalanx with which it articulates.

E T LEDDY, M D

BONE DISEASES (THERAPY)

Metastasis of the "Benign" Giant-Cell Tumor of Bone (Osteoclastoma) S C Dyke Jour Path and Bacteriol, March, 1931, XXXIV, 259-263

The author reports a case of benign giant-cell tumor arising from the lower end of the femur, with metastases in the scalp, lungs, kidneys, ribs, spine, and mediastinal and peritoneal lymph nodes.

The patient was a male, 25 years of age, and the history extended over five years. He had been treated with Coley's fluid, but amputation was eventually resorted to.

The author was able to find recorded only one other case of this type of tumor, with metastases, the authenticity of which could not be questioned.

E C VOGT, M D

CANCER (DIAGNOSIS)

The Biopsy Question Benjamin G P Shafiroff Am Med, November, 1931, XXXVII, 605-608

The author discusses the importance of a biopsy in all lesions in which malignancy is suspected. A biopsy is believed to serve the following functions: To make a differential diagnosis, to aid in outlining the method of treatment, to determine prognosis, and to assist in research of the disease.

The treatment of malignancy varies with the type of pathology present. Surgery, X-rays, radium, or various combinations of these agents are employed, depending upon the condition present. In like manner, the highly malignant types of cancer require more radical treatment than the simple benign tumors. Of great importance before biopsy, however, is preliminary X-ray irradiation of the involved region to prevent direct extension and metastasis through the lymphatics. In certain lesions, such as carcinoma of the breast, all preparations should be made for immediate surgery in the event that the pathologist finds a malignant process.

Lesions of the cervical glands yield important information on biopsy analysis. Diagnosis of tumors of the face and extremities should be corroborated by biopsy. Biopsy is not as valuable in intra-abdominal and intrathoracic lesions, for the X-ray and bronchoscopic examinations reveal valuable information. The author believes that the portion of tissue removed for biopsy should be taken from the periphery of the tumor and should contain healthy tissue as well as the tumor tissue. A negative biopsy report may not mean that the lesion is not malignant, but a positive biopsy is always significant.

J N ANÉ, M D

Cancer of the Thyroid Its Radiosensitivity Cushman D Haagensen Am Jour Cancer (Suppl), July, 1931, XV, 2063-2105

The author studied thirty cases of carcinoma of the thyroid which had received radiation. He found considerable variation in response; these tumors by no means follow the usual laws of radiosensitivity, particularly

from the viewpoint of primary regression and definitive cure.

The various forms of thyroid cancer were grouped into five types, each type having a fairly characteristic natural history and morphologic structure.

The author finds that there is a moderate radiosensitivity in the less anaplastic types, particularly the adeno-carcinoma group. The most rapidly growing and anaplastic types appear to be uniformly radioresistant.

Emphasis is placed on the histologic structure of the tumor as well as size and extent in determining the type of treatment.

JOHN R. CARTY, M D

A Study of Cancer in Ex-service Men. Philip B Matz Med Bull Veterans' Administration, November, 1931, VII, 1010-1031

In a thorough and complete study, the author analyzed 319 cases of malignant diseases which occurred in patients in government hospitals. Of this number, 317 were males and two were females. The series consisted of the following: 259, or 81.2 per cent, carcinomas, 49, or 15.4 per cent, sarcomas, one glioma, two teratomas, and three unclassified tumors.

Since the work of Maud Slye and the studies of Warthin support the opinion that heredity is an etiologic factor in malignant neoplasms, the author studied a smaller group of 52 cases of malignant tumors with a positive hereditary or familial history, or both. It was noted that 69.2 per cent gave an hereditary history of cancer, 21.2 per cent gave a familial history, and 9.6 per cent gave both a familial and hereditary history of cancer.

The most frequent locations of the tumors in this group were: The skin, lip, stomach, lymph nodes, rectum, buccal cavity, and bladder. It likewise was noted as a result of this study that the age period from 35 to 40 was the most critical one for the onset and incidence of malignant disease. No indication of a relationship existing between the type of occupation and cancer of a particular organ or site was observed, except in the group of 48 cases of cancer of the skin or mucous m-

branes In this group it was found that in 25 instances the patients were farmers or ranchers and thus exposed to the actinic rays and outdoor life of their occupations However, of interest is the fact that 128, or 40 per cent, of the 319 cases of malignant disease gave a well defined history of previous irritation or inflammation In the author's opinion, in 76 instances the malignant tumors might be attributable to smoking

In reviewing the clinical records of the series of 319 cases it was found that 88, or 27.6 per cent, gave a history of having had some precancerous condition prior to the actual development of cancer The most frequent early symptoms and signs of malignant disease noted were Tumor formation, pain, ulceration, bleeding, and loss of weight The characteristics of malignant neoplasms were arranged by the author, in their order of frequency, as follows Induration and ulceration, induration, ulceration, tumor formation and induration The rate of growth of the malignant tumors was slow in 62.7 per cent of cases and rapid in 36.1 per cent of the series

The diagnostic methods employed in these cases naturally depended to a large extent upon the organ affected Clinical means and biopsy, therefore, were the most frequent procedures employed in 134 cases of cancer of the skin, mucous membranes, and buccal cavity Clinical means, the X-ray, and exploratory operation were the diagnostic methods employed in 79 cases of cancer of the digestive tract and in ten cases of malignant tumors of bone Likewise, it is of interest that 46 per cent gave a definite history of pain at the onset of the growth, 29.3 per cent developed pain after the onset of the growth, and 24.7 per cent had no pain at any time during the course of the disease

Since the results obtained in the treatment of cancer are in large part dependent upon the early diagnosis and treatment of the disease, the author considered it of importance to study the period of time which intervened between the onset of the malignant process and its recognition and diagnosis In this regard it was noted that 201 patients were treated for various conditions before a diagnosis of malignant tumor was made Of the

201 cases, 105 were treated for periods less than one year and 25 from one to two years In some instances patients were treated as long as twenty years before a diagnosis of cancer was definitely made

Of 319 patients, 112 gave evidence of metastases In a study of the sites of metastases it was found that in the case of carcinoma the sites in the order of frequency were Lymph nodes, liver, lungs, spleen, pancreas, peritoneum, and bones In the case of sarcoma the sites of metastases in the order of frequency were Lymph nodes, lungs, liver, general sarcomatosis, kidney, spleen, ileum, and bones

J N ANÉ, MD

Primary Cancer of the Ovary, with Invasion of the Peritoneum and Pleura Uterine Fibroma Temistocles Castellano and Severo R Amuchástegui La Prensa Méd, Aug 30, 1931, XVIII, 389-396

A woman, 50 years of age, was admitted to the hospital She had been normal until she married, when she developed menstrual disturbances, such as pain, menorrhagia, and metrorrhagia These gradually became worse as she grew older The menopause came on at the age of 47 years Seven months prior to admission, she complained of diffuse pain and heaviness in the abdomen The abdomen seemed to increase in size, there was edema of the inferior extremities, accompanied by weakness and dyspnea She consulted a physician who tapped her, obtained ten quarts of fluid, and advised her to enter the hospital

In the hospital, after being tapped, she was found to have an irregular, hard mass in the epigastrium, extending from the ribs to the umbilicus In the hypogastrum, there was palpated another mass which extended from the umbilicus to the symphysis pubis Still other masses could be felt in the abdomen Radiograms of the chest revealed invasion of the pleura on the right side Biopsy of the abdominal tumor showed malignancy Necropsy findings were a primary tumor of the ovary, with invasion of the peritoneum and pleura, and a uterine fibroma

No indication of a relationship existing between the type of occupation and cancer of a particular organ or site was observed, except in the group of 48 cases of cancer of the skin or mucous mem-

breast with post-operative and without post-operative radiation, has convinced us that (1) the average natural duration of life for a patient with carcinoma of the breast is three years, (2) as a result of radical operation about 38 per cent of the cases will be free from disease for the natural duration of 1½ and about 30 per cent for five years, (3) with repeated superficial doses of radiation, at least ten per cent more patients may be expected to survive the five-year period"

W W WATKINS MD

Carcinoma of the Cervix, with Twin Pregnancy and Normal Delivery J L Blonstein *Lancet*, Oct 24, 1931, CCXXI, 903, 904

The author was called in on an obstetrical case by a midwife because of prolonged first stage. There was very little progress during the next twenty-four hours, but the patient was delivered of a female child followed by a male child three hours later. There was no difficulty in delivery. The male infant developed pemphigus neonatorum on the fifth day and died on the eighth day. The female infant developed a similar condition on the sixth day and died on the ninth day. The mother had a normal postpartum convalescence until the thirteenth day. She had been allowed up on the tenth day. On the fourteenth day she developed pulmonary edema, became comatose, and died. Postmortem examination showed carcinoma of the cervix.

The author reports this case because of the following interesting points. The absence of any symptoms of carcinoma during the pregnancy, the absence of severe postpartum hemorrhage, the viability of the infants, and the probable infection of the infants with pemphigus from the carcinomatous area.

F L GRANDSTAFF, MD

Carcinoma of the Bladder with Vesicorectal Fistula Robert Pollock Urol and Cutan Rev., September, 1931, XXXV, 584-587

Tumors of the bladder, which are more common in males, occur during the period

from the fourth to seventh decades, and are found most frequently at or about the ureteral orifices and bladder outlet. The author believes that a papillary carcinoma frequently begins as a benign papilloma.

The initial symptom of an early carcinoma is generally painless hematuria, due to the following causes. Breaking up of papilla, ulceration and necrosis, instrumentation. The later symptoms are those due to infection, and those which result from obstruction at or near the bladder neck. In advanced stages pain is important, being caused by nerve involvement.

While the diagnosis may be suspected from the history, a careful physical, cystoscopic, and roentgenologic examination should be made. A rectal examination in males, or vaginal and rectal in females, may prove very valuable. Cystoscopy permits the operator to visualize the tumor mass and a cystogram gives information regarding the degree of involvement and extent. Routine X-ray studies of the pelvis, long bones, chest, and skull should also be made.

The author divides the treatment of carcinoma of the bladder into the following procedures: (1) Surgery, (2) high frequency electric treatment, (3) radiation with X-ray or radium, and (4) combinations of these methods.

The case of a male, 67 years of age, who was admitted to the hospital complaining of painless hematuria, is reported. Six months previous to admission a prostatectomy had been performed. Cystoscopy revealed a diffuse redness of the bladder mucosa, with thickening and loss of luster. Finger-like projections from the bladder neck and posterior urethra were seen. Cystography showed a constricted bladder with partial filling of the left ureter. Rectal examination revealed two firm masses occupying the prostatic bed. Radium was implanted into the prostatic bed and the patient was given transfusions and a course of deep X-ray treatments.

The patient was subsequently admitted for a third time, complaining of hematuria, frequency, pyuria, dysuria, and nocturia. Rectal examination at this time revealed a firm irregular mass filling the prostatic cavity. Blood

A Cancer Program for California Lyell C Kinney Calif and West Med, May, 1931, XXXIV, 321-325

The author gives some statistics regarding the increasing rate of cancer and its mortality and believes that the responsibility of the medical profession is greatly increased, due to the fact that the public is becoming cancer-conscious. The cure depends upon early diagnosis and immediate treatment. Most cancer is seen by the general practitioner first, and treatment most often is given by surgeons, whose experience may be limited to a very few cancer patients per year. One of the present problems of the profession is the accomplishment of early adequate treatment by skilled and experienced persons.

The author then notes the preventative measures of cancer by irradiation of the areas of irritation. He believes that the high mortality is due to the fact that most persons do not seek medical advice immediately. Not only must there be early diagnosis, but adequate treatment must be instituted at once, because the curable stage of cancer is very short. Once this time is passed the patient cannot be returned to a stage of curability. In the later stages palliation should be used with skill so as to make the patient more comfortable and to prolong life. Another problem is the education of the family physician to protect his patients from cancer by the treatment of precancerous lesions.

Since the diagnosis involves many technical procedures, and the program of therapy takes the judgment of an internist, a surgeon, a pathologist, and a radiologist, he believes there should be an institution for training and assistance in the diagnosis and treatment of cancer by the general practitioner. Such an institution should also carry out cancer research. The public should be taught that only in early recognition and immediate destruction of the growth lies the hope of cure of cancer.

FRANCIS B SHELDON, MD

Carcinoma of the Lungs Joseph Rothman Med Bull Veterans' Administration, November, 1931, VII, 1044-1047

Primary carcinoma of the lungs is believed

to occur less frequently than the secondary type. MacMahon and Carman collected the records of 482 authentic primary carcinomas of the lungs. Ewing classifies pulmonary carcinoma as follows: (1) Carcinoma arising from the bronchial epithelium, usually of the squamous or cylindrical cell variety; (2) bronchial carcinoma from the mucous glands, found as nodular areas, usually smaller than the other types and located on the walls of the lower end of the trachea or the upper bronchi; (3) carcinoma from the pulmonary alveoli, usually of the cuboid or cylindrical cell variety.

While little is known regarding the etiology of primary carcinoma of the lungs, many authors believe that it is found in old cases of pulmonary tuberculosis. Secondary carcinoma represents the metastatic involvement of the lungs from a primary malignant focus elsewhere. The symptomatology in this condition depends on the location, variety, and condition of development. The differential diagnosis between pulmonary carcinoma and pulmonary tuberculosis is rather difficult in some cases.

J N ANÉ, MD

An Analysis of 1,347 Cases of Malignant Tumors of the Breast, with Special Reference to Management and End-results G W Crile The Journal-Lancet, Feb 1, 1931, LI, 99

Of the cases studied there were 523 available for end-result data, of these 284 (54.3 per cent) showed survival from three to five years, 196 (37.4 per cent) showed survival from five to ten years. With regard to radiation the author states, "Our radiotherapy department, under Dr U V Portmann, and our surgical division are agreed on the following conclusions: our experience testifies against radiation before operation. A course of radiotherapy takes time—usually at least two weeks. Radiation of itself alone cannot entirely cure a case of carcinoma of the breast as securely as a complete surgical excision. As for post-operative radiation, Portmann, by an extensive statistical study of the comparative results of operations for cancer of the

The Diagnosis of Cancer by Spectro-photometry Editorial Canadian Med Assn Jour, September, 1931, XXV, 326, 327

It has long been known that the blood serum of cancer subjects presents biochemical and biophysical peculiarities, as compared with normal serum. The hope has been that it would eventually be possible to devise a reliable specific test for the presence of cancer, based on such peculiarities. This hope has not been realized, but sufficient success has been obtained to warrant a continuation of the quest.

The editor summarizes the work that has already been done along this line, and calls attention to the recent important research of S G T Bendien, of Zeist, Holland, which is attracting much attention at the present time. His technic is as follows:

The serum to be tested is flocculated by various mixtures of acetic acid and sodium vanadate, and the precipitate so obtained is dissolved in a 2 per cent solution of sodium bicarbonate. This solution is then subjected to spectro-photometric analysis. From a series of spectrograms the extinction coefficients are obtained, and from these a curve is plotted on which the diagnosis is based. Bendien does not claim that he can make an accurate diagnosis in every case of cancer, but he does say that a positive reaction is never found in any other disease.

In the light of these findings, Bendien holds to the view that cancer is a local disease which can develop only if a specific abnormality of the serum be present. Should this prove to be true, the implications are far-reaching. Not only may it be possible to diagnose cancer in the early stages but even before it has developed. In other words, it may be possible to detect the predisposition to cancer. Furthermore, it may be possible to determine more fully the biochemical and biophysical derangements that accompany and characterize the cancerous process, which, indeed, may prove to be the cause of cancer. This, at the moment, seems to be mere speculation. Yet, the studies of other workers point in the same direction. The experiments of Maud Slye, in which she was able to produce in animals a

susceptibility of such high degree that 100 per cent developed cancer after the application of a simple irritant, are to the point here. Also, the experimental production of cancer by painting a skin surface with tar has shown that in it there are certain substances that have specific properties, for not every kind of tar will produce cancer.

Bendien's method has been subjected to rigorous test at the instance of the British Empire Cancer Campaign, as recorded by the *British Medical Journal*. Alfred Piney, Secretary of the Investigation Committee of this organization, went to Holland, taking with him thirty-eight tubes of blood serum collected from patients suffering from various diseases. Bendien examined twenty-one of the specimens and of these he diagnosed five as from cancer patients, all of which were correct. The British Empire Cancer Campaign Committee is satisfied that a distinct advance in the diagnosis has been made. Of course, time must be allowed before these findings can be properly appraised. Much more work must be done and by observers in other lands as well. The investigation is being started immediately at the Cancer Hospital in London.

L J CARTER, MD

CANCER (THERAPY)

The Position of Surgery and Radium in the Treatment of Oral Cancer Earl C Padgett Jour Kansas Med Soc, May, 1931, XXXII, 167-172

He who presumes to treat cancer should have a well balanced combination of pathologic, radiologic, and surgical knowledge and should be in a position to use all three. Epidermoid carcinoma in and about the face, mouth, and jaws has a fair prognosis when all phases of the picture are taken, and sound methods of attack used. The end-results depend on the completeness of the eradication of the local lesion and the tributary lymphatic areas. When bone is involved, radium does not effect a cure unless necrosis is produced so that as a rule excision becomes obligatory. Radium will not destroy the metastatic lesions of epidermoid carcinoma. The best methods

examination showed a leukocytosis. In order to ascertain the degree of rectal involvement a barium enema was given and roentgenograms showed visualization of the bladder, right ureter, and kidney pelvis, besides outlining the rectum. The sigmoid appeared irregular and moth-eaten. Pyelography, with intravenous uroselectan, showed faintly outlined pelvis and ureters, as well as bladder and rectum.

J N ANÉ, MD

Exeresis of Carcinoma of the Rectum
Victor Pauchet Rev Medicina y Cirugia,
Habana, Sept 30, 1931, XXXVI, 639-644

The purpose of this paper is to emphasize the necessity of a rectal or proctoscopic examination and to rule out cancer of the rectum as a possible diagnosis in patients complaining of disturbances in defecation, blood in the stools, and a burning sensation in the rectum. Many cases become inoperable because physicians have passed them for cases of hemorrhoids or enteritis. The author goes into detail to show that there could be more operable cases if diagnosis were made early, and that the mortality in those cases is not as high as expected. He advocates the use of radium in inoperable cancer situated low in the rectum and X-ray in those higher up.

N G GONZALEZ, MD

Cancer of the Lung Antony J Greco and
Edwin J Kehoe Med Bull Veterans' Ad-
ministration, September, 1931, VII, 876-883

In 1810, Bayle described the rarest type of pulmonary tuberculosis and this report was considered by Menetrier as the first recorded case of cancer of the lung. Subsequently, other investigators confirmed Bayle's observation that pulmonary tuberculosis is frequently found associated with carcinoma of the lung. It is believed that the incidence of cancer of the lung has increased in recent years, due to the increase in respiratory irritants, which is believed to play some part in the etiology of this condition.

No characteristic symptoms or signs are observed in cancer of the lung. While cough, foul expectoration, hemoptysis, pain, dyspnea,

fever, and cachexia are the outstanding symptoms, the symptomatology depends upon the location of the carcinoma and pressure upon the superior vena cava, the aorta, the heart, the recurrent laryngeal nerves, cervical sympathetic ganglia, trachea, or bronchi. Stivelman has recently shown that the lesion is most frequently found by lung specialists and correctly diagnosed by the X-ray.

It is agreed that the outcome is uniformly fatal in from two months to two years. Treatment is symptomatic, and Jackson believes that X-ray therapy is of palliative value and that this form of treatment causes shrinkage of the tumor and may prolong life for from four to five years.

The authors report a case of primary carcinoma of the lung, which was diagnosed during life, the patient living seventeen months. They also report a case of metastatic sarcoma of the lung, in which case the patient lived only ten weeks after the diagnosis was made.

The primary neoplasm of the lung occurred in a white male, 53 years of age, whose occupation was the oiling and greasing of automobiles. He gave a history of smoking a pipe, cigars, and many cigarettes, but the use of alcohol was denied. The family history was negative for any familial diseases or tendencies. He believed the onset of his illness occurred with fever, chills, cough, and pain in the chest. X-ray examination revealed the following findings: a homogeneous mass occupying the medial two-thirds of the left upper lobe, thickened pleura over the left upper lobe, scattered small densities at the left base, left diaphragm elevated, with a paradoxical movement suggestive of phrenic paralysis. Deep X-ray therapy was immediately ordered and the patient received many complete courses. While he constantly complained of loss of strength, putrid expectoration, and pain, his general condition remained good with no loss of weight for a considerable period. X-ray examination made the day before the patient died showed cavitation in the center of the mass, disseminated infiltration of the right lung, and the vertebral column convexly pushed toward the right side.

**Carcinoma of the Mucosa of the Cheek
Radiation Treatment and Clinical Reports**
Luigi DeVecchi. La Radiologia Medica, December, 1930, XVII, 1399-1432

This article is an extensive clinical report of twenty-eight cases of carcinoma of the mucosa of the cheek observed by the author at the Institute of Radiology of the University and at the Cancer Institute of Milan. He favors radium therapy for the primary lesions of the mucosa and surgical intervention for metastatic adenopathies

L MARINELLI

Radiotherapy in Cancer of the Upper Air Passages W Douglas Harmer Lancet, Nov 14, 1931, CCXXI, 1057-1063

The author circularized a letter to all leading laryngologists and to many prominent clinics, and received seventy replies, the majority of these making it quite clear that radiation treatment had been of little value to them. He thinks that their opinions are due to improper management of the cases and stresses the importance of early diagnosis and treatment by radiation specialists

After X-ray treatment the following post-irradiation changes are noted. Total disappearance of the growth, fibrosis or partial healing, edema, X-ray sores, necrosis, pain, and mortality. There is a short discussion under each heading.

The author discusses the operable, the borderline, and the inoperable groups of malignant tumors of the larynx, the hypopharynx, the nose, nasopharynx, tonsil and mesopharynx, palate, and cheek. Endothelioma and transitional-cell carcinomas and lymphoepitheliomas are treated separately, giving their most common site of appearance.

The author, after reviewing the collected cases of carcinomas, sarcomas, and endotheliomas,

believes there is a great future for radiotherapy if treatment is properly handled. The authorities should prevent agencies from loaning radium to anyone except a recognized expert, and the patient ought not to be handed over to the pure radiotherapist who has no clinical knowledge of the disease that requires treatment. Great palliative relief can be afforded by X-ray treatment to a large percentage of advanced cases of cancer, and it is safer to treat the virulent types of cancer with X-rays rather than with surgery alone.

F L GRANDSTAFF, M D

A Method of Palliative Treatment of Carcinoma of the Esophagus D W Gordon Murray Canadian Med Assn. Jour, September, 1931, XXV, 271-275

Carcinoma of the thoracic esophagus has baffled all attempts at cure, except in a very small number of cases. Treatment by operation has but very few successful reports. Radium and X-ray therapy have been ineffective, partly because of the inaccessibility, and partly because of the common type of growth which is resistant to radiation. Quite massive growths, indicating a fairly late condition, exist in the esophagus without causing marked symptoms. Again, patients with obstruction to swallowing usually carry on with any form of food that will go through. Only when fluids cause difficulty do they seek relief.

All these conditions compose a picture of late malignant disease in an organ that is almost inaccessible, the treatment of which has vexed the medical profession for centuries. Gastrostomy or enterostomy to prevent starvation has been the method of choice in the past, but some have used various methods of intermittent dilatation. Neither of these procedures has been satisfactory even as a palliative.

Consideration of these facts led to a method of treatment for palliative purposes, of the principles of which Simmonds and, later, Souttar, were the first exponents. The aim is to dilate the stricture and pass through its lumen a tube which will prevent closure by spasm or growth. This allows the passage of food in the diet provided it is first

so sustaining the strength of the patient. It also eliminates the symptoms of obstruction and regurgitation of mucus, and precludes the method of feeding by gastrostomy, which prevents the patient from following most occupations and shuts him out from society generally. These benefits give the patient a different attitude towards life and relief from apprehension for the future.

Details of the operation of passing the tube, after dilating the stricture, through the esophagoscope, are given.

In the growths about the level of the bifurcation of the trachea, which comprise about 60 per cent of all esophageal carcinomas, this method may be used in practically all. In the lower part of the esophagus, comprising about 30 per cent, the growths tend to be more vascular and softer in consistency, with a greater tendency for the tube to drop through. Again those at the cardiac end are of the same type, but here one added objection is that the stomach contents regurgitate through the patent cardiac orifice, requiring these patients to be nursed in Fowler's position. Hypopharyngeal and post-cricoid growths are unsuitable.

The contra-indications to this method are advanced constitutional disease, so advanced as to preclude the giving of ether anesthesia, local conditions such as aneurysm of the aorta and tracheo-esophageal fistula, and osteo-arthritis of the cervical region, making full extension of the head impossible.

Ten interesting case reports are appended to the author's discussion. The patients all secured relief from symptoms, namely, obstruction to swallowing and mucus in the throat, for periods up to ten months. All of them, except one, were able to follow their usual occupation. Some were alive at the end of the interval reported, some had died from metastasis elsewhere, some from hemorrhage, and some from other diseases. In no case did the postmortem examination reveal any ulceration caused by the tube.

L J CARTER, M D

Remote Results of Treatment of Cancer of the Rectum Roger Savignac Arch d

mal de l'app digestif, June, 1931, XXI, 710-722

Seventy-three cases are followed and the author's general impression concerning treatment is given. Deep radiotherapy is considered useless and at times dangerous, while the use of radium is useful, especially in inoperable cases or cases refusing operation. Following its application the growth often recedes, and the pain and discharge lessen.

Functional disturbances usually occur for two or three years before the patient seeks relief and then he is likely to die about six months later. Colostomy should be reserved for inoperable cases when defecation becomes painful, tenseness occurs, the discharge increases, and the general condition becomes bad, since this procedure is of no help except when danger of obstruction occurs as indicated above. It should be done if radium therapy is needed, as it can best be applied through the colostomy. The immediate mortality is 30 per cent, among cases not operated upon, 40 per cent. Of the group reported, seven out of twenty-six survived, five of the seven living more than five years—one for nine years and two are still alive after ten years. There is but one chance in three to survive. The results justify the risk on the following conditions: (1) Selection of operable cases on the basis of their ability to resist the extreme shock, (2) age, (3) condition of other organs and general constitution, (4) absence of metastasis, (5) size, location, and mobility of the tumor through rectal manual and proctoscopic examination, and (6) preparation of the patient.

B J DE LAUREAL, M D

Irradiation of Carcinoma of the Cervix Uteri Harry H Bowing and Robert E Fricke Minnesota Med, March, 1931, XIV, 237-244

The results of radiation are fairly constant throughout the world, though the diversity of methods of treatment is surprising. The authors review the methods employed in the following clinics: Regaud's, where continuous irradiation over long periods of time is the distinguishing characteristic, and where,

in a total of 350 patients, 70 per cent of five-year cures were obtained, clinic of Forssell and Heyman in Stockholm, Wintz in Erlangen, who uses roentgen irradiation entirely, Doderlein Clinic in Munich, where combined radium and X-ray are used, at Zurich, where Furst advocates roentgen treatment followed by radical hysterectomy, Radium Institute of Brussels, Baltimore, where Kelly and Burnam give massive doses in one treatment, University Hospital in Philadelphia, Memorial Hospital in New York, Woman's Hospital in New York, Schmitz of Chicago, Huntington Memorial Hospital in Boston, Schreiner of Buffalo, Pomeroy of Cleveland.

The technic at the Mayo Clinic is described, being similar to that many times described by these authors in various publications, their five-year results in cases treated between 1915 and 1924 were published in the March, 1930, issue of *Minnesota Medicine*. The Mayo Clinic method lies between the massive dose and the fractional dose, embodying some of the advantages of each.

W W WATKINS, M D

The Massive Dose and Fractional Methods in Radiation Therapy of Cancer
Leopold Freund *Acta Radiologica*, 1931, XII,
315-336

The author presents a thorough and very interesting history of the development of radiation therapy since 1896. He finds proof of its merit in the fact that it is in high repute thirty-five years after its introduction, and in its extension to new fields.

Soon after Roentgen's discovery, skin changes following exposure to X-rays were observed by men using the new radiation. By 1896, depilation and other changes in the lesions of lupus, unaccompanied by damage to adjacent tissues, were observed. Soon after this, Senn obtained favorable results in leukemia by X-ray treatment and Albers-Schönberg demonstrated experimentally that the testicle could be destroyed without visibly injuring the skin. These early discoveries showed that X-rays had a selective action and stimulated efforts to develop radiation therapy for cancer.

Before long it was found that the actively dividing epithelial cells of a malignant tumor are particularly sensitive to radiation, while the resting cells which are not dividing rapidly are but little affected. This destruction of mitotic cells is due to the direct action of the radiation upon them. Whether or not there is also an indirect action manifested in hyperemia, reactions in the connective tissue of the tumor, stimulation of enzyme formation, etc., is still not definitely known.

Freund states that he regards himself as the first student of radiation to prove the following points: (1) Roentgen irradiation has a biologic action, (2) this action has therapeutic value, (3) radiation possesses also certain dangers, (4) the action of radiation is cumulative. He also recognized early the necessity of large doses and heavy filtration.

It was not many years before the first crude apparatus for generating X-rays was improved and the technical advance begun, which has finally resulted in our modern high tension transformers with their high voltage current and great intensity. This improvement in machinery caused Albers-Schönberg to develop the idea of giving the whole dose of radiation at one sitting and in a few minutes. This was the beginning of the massive-dose technic in therapy.

At this time there were no really accurate methods of measuring small quantities of radiation. However, it was comparatively easy to measure the large amounts used in these single massive doses, hence the exponents of this method considered theirs an accurate way and the fractional method an inaccurate one of administering radiation. In spite of the widespread acceptance of the massive dose technic, there were a number of radiologists—the author being prominent among them—who believed in the fractional method and continued to study and use it.

As early as 1902, the author reported a case of carcinoma of the mouth greatly improved by treatment by the fractional method. During the next twenty years many other similar reports were made concerning recurrent nodes, diffuse carcinoma of the mesenteric glands and the peritoneum, sarcomatous me-

tastases, etc. Although the individual doses in the fractional method were small, the total dose was large and the tissue-effect was more nearly continuous and constant than in single massive doses. The facts that there is no great difference in sensitivity between cancer cells and normal tissue and that the cancer dose must be large rendered damage to healthy tissue more probable in the massive dose method. Furthermore, these large doses did not completely destroy the tumor. Weichselbaum, at autopsy on women treated by massive radiation for carcinoma of the pelvic organs, found that the cancer was not destroyed and that fistulae and necrosis followed the treatment. The patients died in great suffering which was markedly increased by their reaction to radiation.

By 1919, it was established that the biologic action of radiation obeys Schwarzschild's theorem "The effect of radiation is delayed the longer the interval between treatments is in proportion to the single treatment, the shorter the individual treatment, and the smaller the intensity of the radiation." Thus, the biologic action of the fractional method appears gradually rather than suddenly.

In the same year Regaud, during his study of cases of cancer of the tongue in the Radium Institute at Paris, observed in the patients treated with large doses more damage to the normal tissues and less destruction of the tumor than in those treated with small, daily doses. From this time on, the fractional method has grown in popularity. The protracted use of small doses is called the saturation technic.

In the modern saturation method there are several important features: (1) The use of small, individual doses, (2) the prolongation of the radiation, (3) the high total dose, (4) the hardness and homogeneity of the radiation accomplished through heavy filtration and increased distance. The advantages of this method are the increased destructive action on cancer tissue and the decreased local and general reaction to the treatment.

The author considers the prolongation of the radiation as important as the large total dose. During a protracted series of treatments, the tumor remains for a considerable

period in a state of continuous radiation reaction. Research has shown that single organs of the body and even single cells possess varying sensitivity to radiation at different times. Because of this variation in sensitivity, prolonged radiation is likely to be more effective.

Severe local reactions are not seen in the fractional methods, and serious general reactions occur only in moribund patients. The author in his thirty-five years' experience has never had severe general reactions or serious injury to the skin in cases treated by the saturation technic.

In general, the fractional method is peculiarly adapted to carcinoma arising from the pavement epithelium of the skin and tending toward cornification. It is less effective in carcinoma arising from glandular tissue. It must not be imagined that there is no place for massive dose technic in radiation. If the tumor is growing rapidly and possesses high sensitivity, one should give a single, large, destructive dose, disregarding the possible reaction, in order to destroy the tumor quickly and completely. On the other hand, with deep tumors which are not very sensitive and grow slowly, one should use numerous smaller doses, all of which are above the threshold of therapeutic activity. With still deeper, larger tumors that are not very sensitive, larger doses at longer intervals are indicated in order to utilize both the destructive action of the larger individual dose and the selective action of prolonged radiation. In deep-seated lesions one should use heavy filtration and increased tube-skin distance.

No set rules can be formulated for fractional radiation. One of its advantages is that it can be adapted to the type of lesion under treatment. The length of the individual treatments, the length of the intervals, and the total dose will all differ according to the case in hand. The author, himself, has had good results when he has treated patients daily during a period of from fourteen to twenty-one days, using one or several portals of entry, depending on the size and location of the tumor, and employing hard, heavily filtered radiation. He repeats the series, if it seems best, after an interval of from four to six weeks. Freund

gives technical details of the methods advised by Miescher, Coutard, Schwarz, and Schinz. He emphasizes the fact that neither research nor experience has yet said the last word about the optimal size of the single or total dose, the length of the intervals between the treatments, or the duration of the series.

The selective action of the fractional method makes it valuable as a method of supplementing surgical removal of malignant growths, post-operative radiation may destroy malignant cells left behind the surgeon's knife. The author has urged, for many years, the radical surgical removal of neoplasms, followed by fractional radiation of the open, unsutured wound. This method is now beginning to be recognized by both physicians and surgeons.

Fractional radiation does not solve the cancer problem, but it deserves more consideration than it has hitherto received. One must not, however, go to the other extreme of abandoning entirely the massive dose, which has certain definite indications.

A L HART, M D

CHEST (DIAGNOSIS)

The Anteroposterior Projection of Oblique Profile for the Radiologic Examination of Only One Lung Dino Tartagli La Radiologia Medica, December, 1930, XVII, 1388-1395

The author has described the technic elsewhere (*Rev di Radiol e Fisica Med*, 1930, Fasc IV, A). He reproduces several films obtained by this method and points out its advantages, especially in the study of interlobar fissures, of conformation of the dia-phragm, and particularly in the localization of adhesions in therapeutic pneumothorax.

L MARINELLI

Some Considerations of the Interpretation of the Paramediastinal Shadow in a Case of Pulmonary Echinococcosis Luigi Pinelli Archivio di Radiologia, May-June, 1931, VII, 570-579

The author discusses a case of paramediastinal pulmonary echinococcus disease in

which there was nothing to suggest a cyst, the only symptom being the expectoration of bloody sputum. The author made the diagnosis after X-ray examination, and in this paper he discusses the differential diagnosis from a clinical and radiologic point of view, which led him to this conclusion.

E T LEDDY, M D

Two Cases of Exceptionally Long Delay in Eliminating Iodine after Bronchography G Cola Archivio di Radiologia, May-June, 1931, VII, 525-536

The first case was a girl who was examined because of the possibility of bronchiectasis. No bronchial dilatation or pulmonary cavity was revealed on X-ray examination, taken by the author's usual technic. The next day there was no change demonstrable in the bronchial shadows. The condition persisted for a week, when an attack of intense coughing brought on expectoration of the oil mixed with mucus. No untoward effect followed.

The second case showed, by bronchography, cavitation in the left base. The findings persisted for about a month and on the fortieth day there were shown only slight changes in the radiologic picture. These two cases are used by the author to illustrate the harmless ness of the examination.

E T LEDDY, M D

Cavitory Bronchospirochetosis Ferdinand- do Talia La Radiologia Medica, December, 1930, XVII, 1370-1387

The author describes two cases of cavitory spirochetosis of the bronchi. Radiographic ob-servations, practised systematically for three or four weeks, led him to conclude the fol-lowing:

(1) The cure is extremely slow, (2) ra-diographic characteristics are much like those seen in pulmonary abscesses, namely, slight opacity at the center and marked opacity at the periphery, (3) reparation processes take place centripetally, the tracks left may be seen as bands or as stripes of radial shape originating from the cicatricial tissue, (4) ra-

diologic result is bound to guide the observer toward the right diagnosis, provided due attention is paid to biologic control

L MARINELLI

Bronchiectasis in Children Gladys L Boyd Canadian Med Assn Jour, August, 1931, XXV, 174-182

Bronchiectasis has been regarded as a rare condition in childhood, despite the fact that from its earliest recognition as a disease entity its frequent inception in early life has been commented on by those who have studied it Laennec, in 1825, reported a series of cases studied by one of his assistants, Cajol, some ten years earlier In three of his four cases, the symptoms dated from early childhood Very little further reference is made to the disease in the young until the close of the century, when its childhood origin is again referred to by Clark, Hadley, and Chaplin in their monograph on fibroid disease of the lung In 1905, Clive Riviere described 33 cases, 23 of which began before five years of age This author gave a classification of the main types of the disease, and also described its pathology and main methods of production Since this time numerous articles have appeared dealing particularly with the etiology and pathology of the disease, but until 1922, when Sicard and Forestier introduced the use of lipiodol for the depiction of the disease, few have dealt with its clinical course or diagnosis Case reports have been frequent since the discovery of these Frenchmen

The author's report is based on the study of 56 cases observed at the Hospital for Sick Children, Toronto, during the past ten years The diagnosis has been made possible largely by the use of the bronchoscope

The age incidence has been from two months to ten years The sex distribution was about equally divided between the male and the female

The variety of pulmonary conditions with which bronchiectasis is associated makes it difficult to determine the causative factor The consensus, however, assumes the bronchial dilatation to be secondary to some infection or injury of sufficient severity to disorganize the

integrity of the bronchial wall The persistence or severity of the infection, and subsequent infections, then increase the ectasis by the fibrosis produced in healing, or produce further destruction

The following factors led to the disease in the author's cases Bronchopneumonia 23, chronic bronchitis 7, measles and pertussis 5, pertussis alone 5, measles alone 4, influenza 4, empyema 4, tonsillectomy 2, lung abscess 2, cough 2

No specific bacteria have been found In the majority the infection was not only mixed, but the flora varied from time to time in the same patient Cultures of turbid or even purulent fluid aspirated from the paranasal sinuses were at times disappointingly sterile Hemolytic streptococci occurred alone or in combination more frequently than any other organism The close relationship between bronchiectasis and tuberculosis was not brought out in this series

Opinions differ as to the method of production of bronchiectasis, but all agree on its secondary nature Two factors seem to be essential in the production of bronchial dilatation (1) Obstruction of a bronchus, particularly if this be partial, and (2) infection If the former is present without the latter the tendency is toward the production of emphysema rather than ectasis

As to the gross pathology, probably the most striking feature is the degree and density of the pleural adhesions This is seen even in infants Bronchial dilatation develops with great ease in children suffering from bronchopneumonia, particularly in cases in which the latter is caused by measles, pertussis, or influenza

From the standpoint of signs and symptoms, the most characteristic thing about bronchiectasis is said to be the very slight degree of impairment of general health This view, so commonly held, has not been confirmed in this series The children were considerably underweight, pale, and tired easily They were seldom able to attend school regularly, and were subject to periods of exacerbation, when they had to remain in bed

The important symptoms are cough—which

is always present—sputum, hemoptysis, dyspnea, and night sweats. Fever may be entirely absent.

Physical signs are not pathognomonic, in fact, may be entirely absent, except during a flare-up. Shifting of the mediastinum to the affected side may be observed. Clubbing of the fingers and toes is sometimes present. Albuminuria is seldom found.

The diagnosis may be made from the X-ray film. Sometimes the ordinary stereoscopic films may be sufficient to establish the diagnosis. The "honey-combing" seen in the lower lobes is pathognomonic. Fortunately, all cases have not progressed far enough to give this characteristic appearance. In such cases, the suggestive findings are extensive fibrosis, cardiac displacement, blurring of the cardiohepatic angle, enlargement of the hilus glands, with no other evidences of tuberculosis. The absence of these findings does not, however, rule out bronchiectasis.

The greatest aid in the modern methods of diagnosis of bronchiectasis, the injection of lipiodol into the bronchi, is described in detail by the author.

The prognosis is varied. Sometimes there is spontaneous recovery. Sometimes the condition progresses in extent of lesion and effect on the general health of the child. Very seldom does it progress to a fatal termination.

The treatment has been greatly changed in the last two years at the Hospital for Sick Children. Previous to that time the main attention was devoted to improving the general health of the child rather than to any attack on the disease process itself. The plan of treatment at present carried out is as follows. Bronchoscopic examination, with the injection of lipiodol in (a) unilateral cases—pneumothorax, repeated bronchoscopic suction, postural drainage—and in (b) bilateral cases—repeated aspiration, postural drainage, lipiodol.

It is too soon to make any statements as to the results of treatment.

L. J. CARTER, M.D.

Pseudotuberculosis from Bronchospirochetosis of Castellani. G. Cola. Archivio di Radiologia, May-June, 1931, VII, 490-508.

This is a pulmonary lesion first described by Castellani, in Ceylon, in 1905, and which has been subsequently reported not only in the Far East but in most of the countries of Europe. The etiologic agent is the *Spironema bronchialis* of Castellani, which is present in enormous quantities in the sputum and in the bronchial mucosa of patients suffering with this disease. Clinical diagnosis is made by demonstrating the organism. The prognosis is generally favorable.

The treatment consists in the administration of arsenicals, antimony, or iodine. The author reports two cases of this rare disease and discusses the clinical and radiologic findings. The radiographic picture is not pathognomonic, but the essentials in it are marked enlargement of the hilar shadow, accentuation of the lung markings, the presence of striæ and scattered micro-granular spots in the upper half of the lung, and apical opacity and retraction.

The author emphasizes the importance of the recognition of this disease. The article concludes with a bibliography of twenty-two references.

E. T. LEDDY, M.D.

CHEST (GENERAL)

Pleuro-pulmonary Complications Following Costal Fractures. Stefano Bistolfi. La Radiologia Medica, November, 1930, XVII, 1255-1308.

The conclusions reached by the author in a review of 1,800 radiographs of injured workers are as follows:

(1) Pleuro-pulmonary complications, due to fracture or trauma of the ribs, are not very frequent.

(2) The age of the injured may or may not be a factor, because although in youth greater elasticity of the organs diminishes the vulnerability of both ribs and underlying tissues, a greater yielding of the thorax would, on the other hand, cause a larger trauma area (between the ribs and pleuro-pulmonary tissues).

(3) The presence of lesions of the pleura and lungs following fracture of the ribs is a rather common occurrence according to radiologic investigation, it must be admitted how-

ever, that these organs show a very marked resistance to traumatic agents

(4) In healthy subjects, pleuro-pulmonary trauma is followed by local reparative processes, which take place in a short time and in a very satisfactory way, regardless of the seriousness of the lesion

(5) Complications occur in weak patients, especially tuberculous ones

The author advocates the most careful radiologic examination in cases of trauma or fractures of the ribs, so that the danger of impending complications may be effectively reduced in the most favorable period

L MARINELLI

Intrathoracic Neoplasms A A Rowan
Canadian Med Assn Jour, October, 1931,
XXV, 401-407

The author presents case reports of five admissions to Ste Anne de Bellevue Hospital, Quebec, made during the last two years

From a diagnostic standpoint, the author discusses the value of the radiograph. He considers that the value of the information gained from X-ray films and from physical signs, and particularly from the laboratory reports, is of most value from a negative standpoint.

The value of an X-ray film depends upon the area of lung presented to view and the clearness with which detail is brought out. In advanced cases such detail must not be obscured by pleural opacities. But even if only one side of the affected lung is shown clearly the films will be of value, as tuberculosis is usually bilateral, and affects chiefly the upper third. The withdrawal of fluid and its replacement by artificial pneumothorax as a diagnostic measure should be tried.

The chief interest of the radiologist in the author's series lies in the comparison made between the X-ray findings and the autopsy reports.

In the first case the X-ray examination showed a pneumonic area of the right upper lobe, the whole lobe being involved, thickened pleura on right diaphragm, trachea displaced to the right, left lung clear. The films showed an opacity above the interlobar line

which might have been due either to pleurisy or to atelectasis. In the further course of the disease the entire right lung area became opaque from pleural effusion. The diagnosis was pleurisy with effusion, neoplasm on the right side, of bronchial or pulmonary origin, possibly with pleural involvement. Autopsy showed the right lung collapsed below and above the second and third ribs where there was a bridge of lung tissue between. The two pleural cavities so formed contained a quart of thin straw-colored fluid which was not blood-stained. The lung was hard and contained bronchiectatic cavities at the base. Microscopic examination showed primary carcinoma of the right lung, with extension to both layers of the pleura, to the diaphragm, to the mediastinal tissues, and the pericardium. There was also involvement of the diaphragmatic peritoneum and mesentery.

In the second case the X-ray examination showed the following. Outline of heart obscured but enlarged to the left, increased density at the right base, mottled area over both lungs. Appearance might be caused by a new-growth at the right base. A comparison of films taken a month later showed Right diaphragm not made out, ground-glass appearance up to the third and fourth ribs. Star, or cloudy vague-shaped areas seen down to the fifth and sixth ribs, with smaller and similar areas among them. Left Heart shadow very irregular, merging with cloudy and fainter small areas resembling tubercles existing throughout the lung. Diaphragm made out with much haziness above it. Scoliosis of spine to the left. In comparison with the first films there seems to be a great extension.

The autopsy findings showed neoplasm of the right and left lungs, with metastases in the liver and mediastinal glands. Endocarditis is seen best in the aortic cusps. There are dense pleural adhesions. The microscopic findings are primary carcinoma of the right lung, with metastases in the left lung, pericardium, liver, retroperitoneal, and mediastinal glands.

In Case 3, the X-ray examination showed the heart, aorta, and trachea displaced to the left, an appearance of compensatory emphy-

sema of the right lung, left half of the diaphragm invisible, a dense area above it, suggestive of thickened pleura. This appearance might also be caused by fluid. This area extended from the base to the fourth rib in front, the heart shadow was half way out in the field. In two weeks' time the heart, aorta, and trachea were found displaced to the right. The lower two-thirds of the left chest were dense, with the appearance of fluid. In spite of repeated negative sputum examinations for tubercle bacillus, a diagnosis of pulmonary tuberculosis was felt to be the only explanation of the findings.

The autopsy showed a great ragged walled cavity in the lower two-thirds of the left lung. Microscopic examination revealed a primary epidermoid carcinoma of the left lung.

In Case 4, the X-ray examination showed a much enlarged heart, with broadened aortic shadow, suggesting aneurysm and fluid at the right base. Six weeks later the lower two-thirds of the right lung was uniformly dense, suggesting fluid or newgrowth. The heart and great vessel shadows were now of normal size. A diagnosis was made of cancer of the lung.

The author does not give the terminal result in this case.

In Case 5, the X-ray examination showed opacities on both sides of the chest, the upper borders of which were not clear or level. Above the level of opacity at the third rib there were no markings suggestive of tuberculosis or tumor. The heart and mediastinal shadows were almost indistinguishable from the general lower thoracic opacity. The diagnosis was failing cardiac decompensation, myocarditis, and pleurisy.

Autopsy revealed a massive tumor involving the whole anterior mediastinum and growing down over the pericardium. The heart, lung roots, and lungs and pleura were involved. The mediastinal mass was the size of a man's head, and occluded by pressure the great vessels, the esophagus, and the trachea. The microscopic diagnosis was lymphosarcoma.

Regarding the value of the X-ray examination in lung tumors, the author reaches the

conclusion that it is only helpful in proportion as the extent of thoracic contents is visible above pleural opacities, should such be present.

L J CARTER, MD

CONTRAST MEDIA

Effect of the Radio-opaque Substances on the Walls of the Vessels L Docimo L'Ateneo Parmense (Suppl), 1931, III, 42-58

The author believes that the employment of arteriography, when limited to the arteries of the extremities, is of evident value, especially in cases of embolism and obliterative thrombo-angiitis. It is, seemingly, the only method for determining with approximate accuracy the seat of the embolism or the point at which the eventual amputation of a member must be made in order to avoid the danger of excessive mutilation or of cutting into a segment insufficiently nourished, with all the consequences of defective vascularization of the borders.

The problem, however, despite all that has been written on the subject, has not yet been thoroughly studied, especially as regards the radio-opaque substances which should be employed. The opaque substances which have thus far been used for purposes of contrast have varied both in nature and in concentration, this variety seeming to indicate that each of them possesses both advantages and disadvantages, whereas it would be preferable to have recourse to a single substance recognized as the one best adapted to the needs of the case and as the least injurious. An opaque substance, in order to be applicable as a means of contrast in the circulating blood, should be harmless to the organism, should cause no disturbance of the circulation or alteration in the vascular walls, and, in addition, should give a clear image, so as to render the field of exploration distinctly visible.

For purposes of elucidating the problem, the author used dogs to study experimentally the effects, on the vascular walls, of solutions of iodide of potassium, bromide of sodium, iodide of sodium, and uroselectan, when used as means of contrast in arteriography. He found that, while the other substances give

rise to marked vascular alterations, uroselectan does not produce any changes, showing that it is completely neutral as regards the injected vessel

W W WHITELOCK, Ph D

Pulmonary Angiography with Uroselectan Adelchi Salotti Archivio di Radiologia, May-June, 1931, VII, 633-639

The author gives a preliminary report on some studies he has made on the circulation in the lungs and hilum and on the radiologic appearance of the superior vena cava. Some interesting findings were brought out which the author feels will be of greater importance clinically as the technic of the examination is improved

E T LEDDY, M D

The Use of Iodized Oil by the Sanatorium Physician in the Diagnosis of Bronchial Affections Stuart Pritchard Jour Michigan St Med Soc, July, 1931, XXX, 506-508

Each method of visualizing the bronchial tree has its advantages. The supraglottic method is perhaps the least complicated, and most simple and time saving for the sanatorium physician, the clinician, and the radiologist.

This method does not require a trained specialist, and the injection causes the patient less strain and worry and little inconvenience. No ill effects have been observed by the author in six years of experience. The method may be employed in fluoroscopic room, office, or hospital, and any part of the bronchial tree may be visualized. It is useful in long-standing bronchitis of indefinite etiology, in cases of chronic cough with expectoration and no definite X-ray pathology, cases of chronic cough with history of pneumonia or foreign body, and in bronchiectasis. As stated in 1926, contra-indications are acute respiratory infections, acute or active tuberculosis, extensive or advanced pulmonary suppuration in a weak patient, advanced circulatory complications, and recent hemoptysis.

W W WATKINS, M D

DIATHERMY

Diathermy E P Cumberbatch Canadian Med Assn Jour, August, 1931, XXV, 164-167

The only way in which external heat can get into the tissues is by radiation or conduction. The electric current, however, passes through the body and actually generates heat within the tissues. Heat which is generated in this way and distributed through the tissues is known as diathermy.

Currents like the faradic, galvanic, and sinusoidal are quite unsuitable for heating purposes within the body, because they would produce unbearable contractions of the muscles and dangerous changes within the tissues long before they reached a strength sufficient to heat the body. It is necessary, then, to deprive the current of its power to stimulate muscle and nerve and to produce chemical changes. This can be done by making it alternate, or oscillate, about a million times per second. This is known as a high frequency current. Not all high frequency currents will, however, produce a perceptible diathermy. High amperage must be used to produce heat.

The therapeutic properties of high frequency currents are due to heat, and heat only. By means of the diathermy current, the power of heat to relieve pain and spasm, to aid resolution of inflammation, and to assist the tissues in freeing themselves from infection, can be brought about in regions which are beyond the reach of other thermo-therapeutic agents. The therapeutic field of diathermy is, therefore, a wide one.

It is in the treatment of certain diseases of the pelvic organs in women that diathermy has made the most striking advances. By introducing a special electrode into the urethra and completing the circuit by means of a pelvic belt electrode, the part mentioned can be heated to 114° F (the maximum bearable without pain) and freed from infecting gonococci, in about 90 per cent of the cases. The same is true of the cervix uteri, when treated in the same manner. If the infection is not gonococcal, it can be removed in about 80 per cent of the cases. By means of a spe-

sema of the right lung, left half of the diaphragm invisible, a dense area above it, suggestive of thickened pleura. This appearance might also be caused by fluid. This area extended from the base to the fourth rib in front, the heart shadow was half way out in the field. In two weeks' time the heart, aorta, and trachea were found displaced to the right. The lower two-thirds of the left chest were dense, with the appearance of fluid. In spite of repeated negative sputum examinations for tubercle bacillus, a diagnosis of pulmonary tuberculosis was felt to be the only explanation of the findings.

The autopsy showed a great ragged walled cavity in the lower two-thirds of the left lung. Microscopic examination revealed a primary epidermoid carcinoma of the left lung.

In Case 4, the X-ray examination showed a much enlarged heart, with broadened aortic shadow, suggesting aneurysm and fluid at the right base. Six weeks later the lower two-thirds of the right lung was uniformly dense, suggesting fluid or newgrowth. The heart and great vessel shadows were now of normal size. A diagnosis was made of cancer of the lung.

The author does not give the terminal result in this case.

In Case 5, the X-ray examination showed opacities on both sides of the chest, the upper borders of which were not clear or level. Above the level of opacity at the third rib there were no markings suggestive of tuberculosis or tumor. The heart and mediastinal shadows were almost indistinguishable from the general lower thoracic opacity. The diagnosis was failing cardiac decompensation, myocarditis, and pleurisy.

Autopsy revealed a massive tumor involving the whole anterior mediastinum and growing down over the pericardium. The heart, lung roots, and lungs and pleura were involved. The mediastinal mass was the size of a man's head, and occluded by pressure the great vessels, the esophagus, and the trachea. The microscopic diagnosis was lymphosarcoma.

Regarding the value of the X-ray examination in lung tumors, the author reaches the

conclusion that it is only helpful in proportion as the extent of thoracic contents is visible above pleural opacities, should such be present.

CONTRAST MEDIA

Effect of the Radio-opaque Substances on the Walls of the Vessels L Docimo L'Ateneo Parmense (Suppl.), 1931, III, 42-58

The author believes that the employment of arteriography, when limited to the arteries of the extremities, is of evident value, especially in cases of embolism and obliterative thrombo-angitis. It is, seemingly, the only method for determining with approximate accuracy the seat of the embolism or the point at which the eventual amputation of a member must be made in order to avoid the danger of excessive mutilation or of cutting into a segment insufficiently nourished, with all the consequences of defective vascularization of the borders.

The problem, however, despite all that has been written on the subject, has not yet been thoroughly studied, especially as regards the radio-opaque substances which should be employed. The opaque substances which have thus far been used for purposes of contrast have varied both in nature and in concentration, this variety seeming to indicate that each of them possesses both advantages and disadvantages, whereas it would be preferable to have recourse to a single substance recognized as the one best adapted to the needs of the case and as the least injurious. An opaque substance, in order to be applicable as a means of contrast in the circulating blood, should be harmless to the organism, should cause no disturbance of the circulation or alteration in the vascular walls, and, in addition, should give a clear image, so as to render the field of exploration distinctly visible.

For purposes of elucidating the problem, the author used dogs to study experimentally the effects, on the vascular walls, of solutions of iodide of potassium, bromide of sodium, iodide of sodium, and uroselectan, when used as means of contrast in arteriography. He found that, while the other substances give

the presence of air spaces in the phantom, within the medium they cause changes of the order of plus 17 per cent for air spaces located above the ionization chamber and of the order of from -4 to -6 per cent for lateral or underlying air spaces

The author thinks, however, that, considering the conditions usually encountered in roentgenotherapy, measurements obtained from phantoms supply the values of doses at different depths of the human body with a reasonable degree of approximation

L MARINELLI

What Is the Ovarian Dose in r Units?
Heinrich Martius *Strahlentherapie*, Sept 12, 1931, XLII, 160-164

The author has made an attempt to determine the average dose expressed in r necessary to bring about amenorrhea in women. He emphasizes that the figure derived from his statistical studies has no absolute significance, because too many variable factors enter into this problem. However, he comes to the conclusion that 290 r effective in the ovaries will in all probability sterilize the majority of women

ERNST A POHLE, M D , Ph D

On the Principles of Balneologic Radium Therapy Quantitative and Energetic Considerations of the Problem of Physiologic Dosage in Emanation Therapy Jaromir Markl *Strahlentherapie*, Oct 3, 1931, XLII, 249-280

The author analyzes in this paper the problem of dosimetry in emanation therapy, if the emanation is applied through contact (as a bath), taken in solution *per os* or inhaled through the lungs. He determined the amount of emanation in the blood for several hours after the administration and plotted the curves. This permitted the calculation of the energy per cc and second in erg. Following a bath in water charged with emanation the concentration in the blood increases up to a maximum and then slowly decreases. After four hours the major amount of the emanation has disappeared from the blood and only a small amount of activity remains.

Two types of curves were seen following application by mouth, one type with a steep slope and one with a very gradual slope. The rise of the emanation in the blood is rather rapid and reaches its maximum within a few minutes. The excretion varies considerably and is sometimes finished within an hour, sometimes taking more than two hours. The author states that after drinking about 200,000 ME, approximately 10,368 alpha particles are effective in 1 cc of tissue during a two-hour period, this corresponds to an energy of 1.73×10^{-5} erg per second and cubic centimeter. In the emanatorium the concentration of the emanation in the blood increases slowly and reaches its maximum after an hour. It drops rapidly as soon as the patient has re-entered a room with ordinary air. Within four hours the greater part of the emanation has been excreted. As to the effectiveness of the three methods of administering emanation, it seems that the emanatorium where the emanation is inhaled takes first place. The author also discusses the possible mechanism of the action of emanation on the organism.

ERNST A POHLE, M D , Ph D

Suppurative Otitis Media. Pedro L Errecarrt *Rev Med Cubana*, October, 1931, XLII, 1218-1228

In this article the subject of suppurative otitis media is thoroughly discussed from etiology to treatment.

The description of the necessary otoscopic examination is particularly instructive and quite complete. The author further discusses the differential diagnosis in detail, naming the most common conditions to be differentiated, and goes on to describe each condition.

In complicated cases in which the otolaryngologic methods of examination are not sufficient to accurately diagnose a condition, the author resorts to X-ray as a means of examination and finds it most valuable in determining or ruling out the presence of mastoiditis.

JOSEPH MALDONADO, M D

THE ESOPHAGUS

Esophageal Spasm in the Child Enrico

cial vaginal electrode it is possible to remove infection of the fallopian tubes and the pelvic supporting tissues in the great majority of cases. Congestive dysmenorrhea can always be cured by diathermy, but the spasmodic type is only temporarily benefited.

In male subjects, the prostate and vesicles can be subjected to diathermy by way of a special electrode. This treatment will always bring gonorrhreal fibrosis or arthritis to an end. In anterior urethritis diathermy has no special value, but in gonococcal epididymitis and orchitis its action is remarkable.

There is sufficient evidence now to show that extracardiac diathermy is valuable in angina pectoris. In cases of hypertension the action of diathermy is to lower blood pressure and relieve the symptoms.

In some cases of chronic bronchitis the application of diathermy to the chest gives lasting relief. The same results have been obtained in some cases of idiopathic asthma. In lobar pneumonia, diathermy can relieve pain and produce sleep after all other methods have failed. It is of great value in mucous colitis.

Diathermy is of great value in surgery. Both malignant and innocuous growths can be heated and their temperature raised until the tissue proteins coagulate. This form of treatment has many advantages. There is no disturbance of the anatomic continuity of the growth, no cutting or scraping, and no loss of blood. The vessels are sealed. The patient does not suffer from shock after the operation. The resulting slough is quickly replaced by granulations, and the resulting scar does not shrink or form adhesions.

Latest developments are the diathermy knife and fulguration.

L. J. CARTER, M.D.

DOSAGE

Energy Distribution in Deep Roentgen Therapy Arduino Ratti. *La Radiologia Medica*, November, 1930, XVII, 1213-1250

The author reviews briefly the work done in the field of roentgen dosimetry and the differential methods employed, giving a comprehensive picture of the errors which are apt to occur in determinations of this sort. His in-

vestigations were performed with a 155 KV constant potential machine, a HVL of 0.85 mm of Cu and under a filtration 0.5 mm of Cu plus 3.0 mm of Al. They consist of:

(1) Determination of the amount of secondary radiation present at the surface of a scattering medium (paraffin block 30 X 30 X 20 cm). This test was performed with five different dosimeters and showed an increase of from 36 to 43 per cent of the primary intensity at a TSD of 30 cm with 6 X 8 cm field to 63 per cent with a field of 20 X 20 at 40 cm TSD.

(2) Determination of the intensity at a depth of 10 cm, expressed in percentage, of the intensity at the surface; the results range from 28 per cent for 6 X 8 cm field, TSD equals 30 cm, to 48 per cent for a 20 X 20 field at 40 centimeters.

(3) Determination of the ratio of the intensity of the beam emerging from a given part of the human body to the intensity of the X-ray beam at the surface; this experiment was performed with the intention of checking the reliability of the results obtained in paraffin. No mention is made of the procedure followed, although the author admits that measurements on the body cannot be considered as technically exact as those made on the phantom; results, however, show no large discrepancy between the tests.

(4) Investigation of the conditions which are apt to decrease the intensity in a scattering medium.

This experiment includes the determination of absorption of vertebrae as compared with that of rice. No remarkable difference was found and indirect experiments confirm the belief that a large increase in the density of bones would not have affected the results.

Any effect due to the presence of bodies of high density (Cu, Pb, etc.) decreased as the size of the irradiated field was increased. The same general considerations apply to the study of "depth dose" in the skull.

(5) Investigation of the conditions which are apt to increase the intensity in a heterogeneous medium.

The conclusions reached are: The change in surface intensity is not affected appreciably by

the presence of air spaces in the phantom, within the medium they cause changes of the order of plus 17 per cent for air spaces located above the ionization chamber and of the order of from -4 to -6 per cent for lateral or underlying air spaces

The author thinks, however, that, considering the conditions usually encountered in roentgenotherapy, measurements obtained from phantoms supply the values of doses at different depths of the human body with a reasonable degree of approximation

There is sufficient evidence now to show that cardiac diathermy is valuable in angina pectoris. In cases of hypertension the action of diathermy is to lower blood pressure and relieve the symptoms.

In some cases of chronic bronchitis the application of diathermy to the chest gives lasting relief. The same results have been obtained in some cases of idiopathic asthma. In lobar pneumonia, diathermy can relieve pain and produce sleep after all other methods have failed. It is of great value in mucous colitis.

Diathermy is of great value in surgery. Both malignant and innocuous growths can be heated and their temperature raised until the tissue proteins coagulate. This form of treatment has many advantages. There is no disturbance of the anatomic continuity of the growth, no cutting or scraping, and no loss of blood. The vessels are sealed. The patient does not suffer from shock after the operation. The resulting slough is quickly replaced by granulations, and the resulting scar does not shrink or form adhesions.

Latest developments are the diathermy knife and fulguration.

L. J. CARTER, M.D.

DOSAGE

Energy Distribution in Deep Roentgen Therapy Arduino Ratti La Radiologia Medica, November, 1930, XVII, 1213-1250

The author reviews briefly the work done in the field of roentgen dosimetry and the differential methods employed, giving a comprehensive picture of the errors which are apt to occur in determinations of this sort. His in-

vestigations were performed with a 155 KV constant potential machine, a HVL of 0.85 mm of Cu and under a filtration 0.5 mm of Cu plus 3.0 mm of Al. They consist of:

(1) Determination of the amount of secondary radiation present at the surface of a scattering medium (paraffin block 30 X 30 X 20 cm). This test was performed with five different dosimeters and showed an increase of from 36 to 43 per cent of the primary intensity at a TSD of 30 cm with 6 X 8 cm. field to 63 per cent with a field of 20 X 20 at 10 cm TSD.

(2) Determination of the intensity at a depth of 10 cm, expressed in percentage, of the intensity at the surface, the results range from 28 per cent for 6 X 8 cm field, TSD equals 30 cm, to 48 per cent for a 20 X 20 field at 40 centimeters.

(3) Determination of the ratio of the intensity of the beam emerging from a given part of the human body to the intensity of the X-ray beam at the surface, this experiment was performed with the intention of checking the reliability of the results obtained in paraffin. No mention is made of the procedure followed, although the author admits that measurements on the body cannot be considered as technically exact as those made on the phantom, results, however, show no large discrepancy between the tests.

(4) Investigation of the conditions which are apt to decrease the intensity in a scattering medium.

This experiment includes the determination of absorption of vertebrae as compared with that of rice. No remarkable difference was found and indirect experiments confirm the belief that a large increase in the density of bones would not have affected the results.

Any effect due to the presence of bodies of high density (Cu, Pb, etc.) decreased as the size of the irradiated field was increased. The same general considerations apply to the study of "depth dose" in the skull.

(5) Investigation of the conditions which are apt to increase the intensity in a heterogeneous medium.

The conclusions reached are: The change in surface intensity is not affected appreciably by

which prevents or hinders spontaneous precipitation in rabbit serum

(2) Flocculation is the result of physical or chemical conditions which are progressively established by anaphylactic process

(3) Radiation, by opposing the establishment of these conditions, decreases both flocculation and anaphylactic charge, including the physio-pathologic phenomena of crisis and shock

(4) Similar action of radiations on serum *in vitro* lends credence to the existence of antagonistic action of X-rays on the colloidal state of vital plasms independently of any cellular activity

L MARINELLI

Application of Radio-active Substances with Long Half Life Period in Medicine. A Ostrčil and F V Novák *Strahlentherapie*, Oct 3, 1931, XLII, 291-306

This is a preliminary report of experiments with a silver emulsion containing a radio-active deposit, which was injected in five cases with malignant tumors. The authors were particularly interested in obtaining a preparation with an activity of long duration. The ionization measurements and animal tests leading to the development of the preparation are briefly discussed. Although no definite statements as to the efficacy of this injection treatment can be made, the authors feel justified in continuing their work

ERNST A POHLE, M D , Ph D

Tissue Metabolism Following Roentgen Exposure Experimental Investigations on the Liver and Kidney J Heeren and J Pansdorf *Strahlentherapie*, Oct 3, 1931, XLII, 307-327

The authors studied the metabolism of tissue following irradiation. Liver and kidney of mice and rats were used for the determinations, which were carried out with the method of Warburg (manometer method). The roentgen exposure was given over the entire abdomen. The technic was as follows 185 KV 5 ma 0.5 mm Cu, 30 cm TSD, 550 r (in air). The amount of oxygen used by liver and kidney tissue was determined immediately

and one hour following irradiation. If the tissue had been suspended in Ringer's solution, there was always a definite increase in the oxidation, both in liver and kidney tissue, lasting about 40 minutes. This increase was not found when the tests were carried out at a later time. The increase of the oxidation depended also upon the dose. If horse serum was used for the suspension of the tissue, the increase in oxidation could not be demonstrated regularly

ERNST A POHLE, M D , Ph D

Some Effects of Ultra-violet Rays on the Vitamin D Content of Plants as Compared with the Direct Irradiation of the Animal Mary Lojkin Contrib Boyce Thompson Inst, 1931, III, 245-265

Standard white rats are fed a rickets-producing diet and tested for their response to sunlight, to ultra-violet irradiation, and to the curative effect of vegetables grown under different conditions. The amount of calcification was estimated by the AgNO_3 line test or by determination of percentage of ash in the femur

Greenhouse plants did not produce Vitamin D. Ultra-violet rays from the sun and from the Hg vapor lamp impart antirachitic value to lettuce, alfalfa, spinach, and soy-bean, but none to cabbage. Greater antirachitic properties are imparted to the cut than to the intact plant. Such antirachitic activation is not destroyed in twenty-four hours. Complete protection was afforded rats exposed to the rays of the Hg vapor lamp for one minute per day. The wave length most effective is that within the limits of solar radiation. The time required for sunlight protection varies with the season. The exposure necessary to produce Vitamin D in the plant is proportionately longer than that required to impart protection by irradiation of the animal

CHEMICAL ABSTRACTS

The Repair *in Vitro* of Embryonic Skeletal Rudiments after Experimental Injury Janet S F Niven Jour Path and Bacteriol, May, 1931, XXXIV, 307-324

Benassi La Radiologia Medica, November, 1930, XVII, 1334-1345

This is a description of two typical cases of this anomaly which is extremely rare in children. The patients were six- and seven-year-old girls. In both, the location of the spasm corresponded to the esophageal hiatus of the diaphragm. The author attributed its presence to nervous or hysterical phenomena in each case, his hypothesis being confirmed by the excellent results obtained by the administration of bromides and belladonna.

L. MARINETTI

EXPERIMENTAL STUDIES

Susceptibility to Tumors Some of the Factors Governing the Same Charles L. Connor Calif and West Med., May, 1931, XXXIV, 325-329

The inoculable tumor may be transmitted by filtered juice or dried, presumably dead tissue, but the transplantable tumor requires living cells. The purpose of the paper is to point out the laws governing these tumors, to indicate an analogy between experimental and human tumors, and to show how experimental factors may be altered.

The adaptation of the Rous fibrosarcoma to various strains of chickens is noted as an adaptation of tumor cells to animals, and in the adaptation of animals to tumors, reference is made to the Sive strain of mice and to the Buffalo strain.

The laws governing the transplantation of normal tissue are noted. But because of lack of genealogic knowledge, the factors regarding human-tumor susceptibility are less well-defined. There has been very little transplanting of human tumors.

Under the general subject of spontaneous retrogression of tumors an etiology has not been proven, and the chance of systemic therapy is very remote if the cause be found to be racial or hereditary. A number of factors is given which will alter the rate of growth or the susceptibility to tumors. The wide variety of methods used, the number of different species of animals studied, and the variation in types of tumors which are affected in different ways by the same substances indi-

cate also that probably no single substance or method will ever be found that will have a uniform effect on all tumors.

FRANCIS B. SHELDON, MD

Some Biologic Effects of Radio-active Substances Study No 1—Effects on a Transplantable Mouse Carcinoma John W. Spies Am Jour Cancer (Suppl.), July, 1931, XV, 2173-2181

The author gave uranium-thorium mixture intravenously and subcutaneously to mice bearing Twort transplantable mouse carcinoma. He concluded that the radio-active substances accelerated the increase in volume of the neoplasm. This in turn shortened the span of life. The factors of necrosis, hemorrhage, and liquefaction could not be ruled out. Large doses of the uranium-thorium mixture produced acute nephritis in some instances, but small doses produced no anatomic lesions of the viscera.

JOHN R. CARTY, MD

Some Biologic Effects of Radio-active Substances Study No 2—Effects on the Normal Rabbit John W. Spies Am. Jour Cancer (Suppl.), July, 1931, XV, 2182-2201

The author found that normal rabbits when injected with a uranium-thorium mixture showed no weight changes and there were no constant blood cell changes. There was a questionable lowering of the blood sugar level, but the cholesterol and blood non-protein nitrogen were probably not altered. Fecundation was not suppressed. There were questionable lesions superimposed on a previously existing spontaneous nephropathy.

JOHN R. CARTY, MD

Serum Anaphylaxis and Rays Luigi Capelli La Radiologia Medica, November, 1930, XVII, 1308-1316

This is an experimental study which follows many others by the same author on the investigation of the mechanism of the action of roentgen rays. The following conclusions may be drawn from it:

(1) Roentgen radiation tends to develop a physical and chemical action on vital colloids

Visualization of the Cornea Hugo Ahlbom
Acta Radiologica, 1931, XII, 212-235

The author reviews all the past work on the localization of foreign bodies in the eye and, describing his method of localization, attempts to show its superiority over Sweet's method. Like Sweet, he attaches no contact markers to the eyeball.

In the Sweet method, the location of the foreign body is not gained directly from the plate, but is arrived at by a geometric computation of displacement with different projection angles, while in the author's method, the plates themselves show clearly in lateral and anteroposterior projections the actual position of the foreign body.

In the anteroposterior view, he uses a wire ring so placed that its center is in line with both the tube focus and the center of the pupil. He thus determines the relation of the foreign body to the center of the eye. In the profile view, obtained by an oblique position of the head and fixation of eyeball at right-angles to the X-ray beam, he uses an aluminum wedge against the cassette to make the cornea visible for a landmark. He thus determines the depth of the foreign body. Every detail necessary for the adoption of the method he explains carefully and for each step he gives the justification.

He points out the following disadvantages of Sweet's method:

(1) An expensive apparatus is necessary and the adjustments are complicated. The author, on the other hand, uses only appliances that are to be found in the regular laboratory equipment and which require no complicated adjustments.

(2) The short target-film distance causes some distortion, as much as 3 mm being produced when the foreign body is situated far back in the eyeball. The author uses a tube-film distance of nine feet and there is no distortion.

(3) The patient may alter the direction of vision during exposure, as there is no means for directly observing him at this time. A comparatively slight change in the direction of vision results in considerable error. With the

author's method, the patient is closely observed while the film is being taken.

NATHAN FLAX, M.D.

Foreign Bodies in the Air Passages Their Diagnosis and Removal William B Faulkner and Edward C Faulkner Calif and West Med, July, 1931, XXXV, 12-18

A history of aspiration is often overlooked but usually is very significant. The physical findings will depend, to a great extent, on the type of obstruction to the air flow, the position of the foreign body, and the amount of obstruction. The location and amount of secretion, also, will have a great deal to do with the physical findings. X-ray (fluoroscope and film) findings are very important. If the foreign body is opaque to the ray, it is easily located.

In non-opaque foreign bodies the diagnosis will depend on changes in the lung, which, in turn, will depend on whether or not the air passage is obstructed. If there is no obstruction by the non-opaque foreign body, the X-ray findings may be entirely negative. Then bronchoscopy must be resorted to. The authors discuss this procedure and the mechanics of foreign-body removal. The sooner the foreign body is removed, the less chance there is of complications.

FRANCIS B SHELDON, M.D.

GALL BLADDER (NORMAL AND PATHOLOGIC)

Indications for Cholecystic Surgery A R Monroe Canadian Med Assn Jour, September, 1931, XXV, 276-279

The object of the author is expressed as an attempt to adjudicate on the various methods of diagnosing cholecytic disease. Once disease of the gall bladder is established the organ should be removed. The results of gall-bladder surgery are so satisfactory that we may justly claim that the rules governing surgery of the appendix should apply to the gall bladder.

The history is important. Often in gall-bladder disease the history is sufficient to en-

In order to study the part played by the various constituents in the repair of bone following injury, owl and mouse embryonic rudiments were cultivated *in vitro*.

It was found that results depend greatly on the period of embryonic life at which the injury is made.

For a detailed description of the processes that occur and the excellent accompanying photomicrographs reference should be made to the original article.

E C VOGT, M D

The Effects of Repeated Intrapleural Injections of Electrolytes in the Rabbit—Acquired Insensitiveness of the Lung Epithelium to a Proliferative Stimulus The Bearing of the Observations on Tissue Resistance J S Young *Jour Path and Bacteriol.* May, 1931, XXXIV, 357-377

Hyperplasia of the epithelium lining the marginal alveoli of the lung of the rabbit can be produced by a single intrapleural injection of $\frac{3}{4}$ N solution of strontium chloride. A second injection within fifteen or twenty days of the first fails to produce further reaction but at a longer interval it becomes effective again.

If injections are started with weak solutions intercurrent hyperplasia can be prevented and finally no reaction is produced by an injection of N/1 solution which would otherwise cause a severe reaction.

The reaction is not strictly specific, as calcium chloride affords some protection against strontium chloride.

It is concluded that these observations are consistent with the hypothesis that cell-division is initiated by precipitation of the colloids of the cell membranes.

E C VOGT, M D

Anaphylaxis and Rays Alkaline Reserve Luigi Cappelli *La Radiologia Medica*, December, 1930, XVII, 1361-1369

This article is essentially a review of the results obtained by the author on a long series of experiments performed on rabbits and human beings, which were previously published in the same journal. He concludes that,

aside from a tendency to produce alkalinity in serum irradiated *in vitro*, roentgen radiation does not produce any noticeable change in alkaline reserve, pH, chloride content of the blood, or acidity in urine.

L MARINELLI

Experimental Rickets T Skaar *Acta Pediatrica*, 1931, XII, Supp I, 1-136

This article occupies the entire supplement and gives in detail the extensive investigations of the author on the calcium, phosphorus, and magnesium metabolism in rickets. The purpose of these experiments was to examine calcium and phosphorus metabolism during the development, existence, and improvement of experimental rickets. Puppies were used as test animals. The experiments are well controlled and have to do with the effect of vitamin deficiency as well as the mineral intake. Some observations are also made on the effect of Vitamin C on the calcium and phosphorus metabolism.

The article is published in English and is accompanied by a comprehensive bibliography.

E C VOGT, M D

THE EYE (DIAGNOSIS)

Metastasis in the Sheath of the Optic Nerve from Carcinoma of the Stomach Isadore Goldstein and David Wexler *Archiv Ophthalmol.*, September, 1931, VI, 414-419

The authors report a case of ulcerating carcinoma of the stomach metastasizing to the abdominal viscera and peri-aortic glands and the sheath of the optic nerve, with absence of visual disturbances. The invasion was probably through the blood stream. They report four cases on record, previous to 1922, arising from carcinoma of the breast, kidney, and bronchial glands, but none from gastric carcinoma.

RAYMOND V MAY, M D

FOREIGN BODIES

A New Method of Localizing Foreign Bodies in the Eye Teleradiography with

Visualization of the Cornea Hugo Ahlbom
Acta Radiologica, 1931, XII, 212-235

The author reviews all the past work on the localization of foreign bodies in the eye and, describing his method of localization, attempts to show its superiority over Sweet's method. Like Sweet, he attaches no contact markers to the eyeball.

In the Sweet method, the location of the foreign body is not gained directly from the plate, but is arrived at by a geometric computation of displacement with different projection angles, while in the author's method, the plates themselves show clearly in lateral and anteroposterior projections the actual position of the foreign body.

In the anteroposterior view, he uses a wire ring so placed that its center is in line with both the tube focus and the center of the pupil. He thus determines the relation of the foreign body to the center of the eye. In the profile view, obtained by an oblique position of the head and fixation of eyeball at right-angles to the X-ray beam, he uses an aluminum wedge against the cassette to make the cornea visible for a landmark. He thus determines the depth of the foreign body. Every detail necessary for the adoption of the method he explains carefully and for each step he gives the justification.

He points out the following disadvantages of Sweet's method:

(1) An expensive apparatus is necessary and the adjustments are complicated. The author, on the other hand, uses only appliances that are to be found in the regular laboratory equipment and which require no complicated adjustments.

(2) The short target-film distance causes some distortion, as much as 3 mm being produced when the foreign body is situated far back in the eyeball. The author uses a tube-film distance of nine feet and there is no distortion.

(3) The patient may alter the direction of vision during exposure, as there is no means for directly observing him at this time. A comparatively slight change in the direction of vision results in considerable error. With the

author's method, the patient is closely observed while the film is being taken.

Foreign Bodies in the Air Passages.
 Their Diagnosis and Removal William B
 Faulkner and Edward C Faulkner Calif
 and West Med, July, 1931, XXXV, 12-18

A history of aspiration is often overlooked but usually is very significant. The physical findings will depend, to a great extent, on the type of obstruction to the air flow, the position of the foreign body, and the amount of obstruction. The location and amount of secretion, also, will have a great deal to do with the physical findings. X-ray (fluoroscope and film) findings are very important. If the foreign body is opaque to the ray, it is easily located.

In non-opaque foreign bodies the diagnosis will depend on changes in the lung, which, in turn, will depend on whether or not the air passage is obstructed. If there is no obstruction by the non-opaque foreign body, the X-ray findings may be entirely negative. Then bronchoscopy must be resorted to. The authors discuss this procedure and the mechanics of foreign-body removal. The sooner the foreign body is removed, the less chance there is of complications.

FRANCIS B SHELDON, M D

GALL BLADDER (NORMAL AND PATHOLOGIC)

Indications for Cholecystic Surgery. A R Monroe Canadian Med Assn Jour, September, 1931, XXV, 276-279

The object of the author is expressed as an attempt to adjudicate on the various methods of diagnosing cholecystic disease. Once disease of the gall bladder is established the organ should be removed. The results of gall-bladder surgery are so satisfactory that we may justly claim that the rules governing surgery of the appendix should apply to the gall bladder.

The history is important. Often in gall-bladder disease the history is sufficient to en-

able one to make a diagnosis without laboratory tests, and will almost always attract our attention to this organ when not sufficient to convict it of harboring disease.

The physical examination may reveal much or little. In most cases the history and physical signs are sufficient on which to make a diagnosis.

Cholecystography is a test of function rather than an estimation of disease. The functions of the gall bladder of which this test is an estimate are the ability to receive bile from the liver by way of the cystic duct, to concentrate and absorb it, and to empty it. The accuracy of the method is estimated at from 89 to 91 per cent. It would appear that cholecystography, although useful, has its limitations, and should be used as an assistant method in the diagnosis of cholelithic disease where symptoms are not definite and the diagnosis is obscure. This is often the case in chronic cholecystitis without stone.

Blood chemistry is important. The estimation of blood bilirubin is just as important in certain cases of cholelithic disease as a blood sugar test is in pancreatic disease. Frequent records of the van den Bergh test, kept graphically, will reveal a bilirubin curve. In a rising curve, the danger from hemorrhage, in the case of operation, is indicated. A falling curve indicates greater safety in operation, the danger of hemorrhage being lessened.

I. J. CARTER, M.D.

Is a Diagnosis of Strawberry Gall Bladder Possible? A Clinical and Radiologic Study L. Feci and E. Ruggieri. *L'Ateneo Parmense* (Suppl.), 1931, III, 439-487

This is an exhaustive clinical and radiologic study of nine cases of strawberry gall bladder. Two distinct classes of facts are given consideration in the radiologic examination. Those which result from observation of the digestive tube (especially of the gastro-duodenal tract), and those resulting from the cholecystographic examination. These two classes of findings show mutual interdependence and complete each other.

It must in truth be recognized that in the majority of cases the Graham test attains its

maximum value insofar as the results are supported and strengthened by direct radiographic examination of the gastro duodenal tract. However, there no longer exists any doubt in the minds of investigators as to the necessity of this combined method of examination of the biliary channels.

The authors make no claim to a categorical solution of the difficult problem which they have undertaken, contenting themselves with mere presentation of the results of their investigations.

Clinically, the disease is encountered primarily in young women, and is of short duration. It shows generally a painful gastralgic, atypical symptomatology (continuous rather than periodic pain).

Radiologically, the syndrome is that of indirect cholecystitis, the Graham test shows signs of diminished resorptive activity (retardation, rarely absence of the appearance of the image), morphologic alterations (non-uniform pallor, blending and irregularity of outlines, deformations) and functionally the disappearance of the images more quickly than normally, at times very rapidly.

W. W. WHITELOCK, Ph.D.

The Intravenous Administration of the Gall-bladder Dye for Diagnosis G. T. Nordin. *The Journal-Lancet*, Jan. 15, 1931, LI, 41-43

Films are made previous to the administration of the dye to see if the gall bladder or stones will visualize. This is the most important part of the examination. The dye is then administered and films are made five or fifteen hours later. A fatty meal is then administered and films are made two hours later.

A gall bladder is considered normal if it is not visualized prior to dye, if it fills within five hours, and decreases to one-fourth its former size after the fatty meal. Any gall bladder visualized before dye is given is abnormal, whether or not it subsequently fills. In 281 cases, 270 were found to be pathologic from X-ray findings, 36 of these showed stones prior to dye, 67 showed stones after dye. At operation, 268 of the cases showed

pathologic gall bladders, of these 221 had stones Two patients were considered normal by the surgeon

W W WATKINS, M D

GASTRO-INTESTINAL TRACT (DIAGNOSIS)

False Aneurysm of the Abdominal Aorta
W A Lincoln Canadian Med Assn Jour,
August, 1931, XXV, 197.

This is a case report of a patient, F B, a white male, aged 42, who had syphilis about twelve years before He had good health until nine months previous to examination, when he developed vague abdominal discomfort, gas, and indigestion About two months before, while pitching hay, he developed very severe pain in the left abdomen, running down into the leg, and collapsed for a few hours Examination at this time did not reveal any abnormality of the abdomen or left flank, and no definite diagnosis could be made About a month later he developed a mass in the left flank, which increased in size until it filled the whole left abdomen, protruding noticeably in the flank and a little behind it This extended up over the ribs and down to Poupart's ligament It had a decided cystic feeling and gave an expansile pulsation There was no bruit or thrill Pulsation was present in the tibialis, posterior tibial region There was no swelling or discoloration of the leg The Wassermann reaction was positive, blood count examination practically normal A pyelogram of the left kidney was normal, although the kidney was displaced upward A barium enema showed the colon to be normal and running over the top of the mass X-ray examination showed some erosion of the first three lumbar vertebrae The patient ran a slight temperature, suffered severely from a boring pain, and failed rather rapidly, dying from exhaustion about four months after the onset of the first pain

The postmortem examination revealed a large sac, practically filling the whole left side of the abdomen, with the colon lying over the top of it and the kidney pushed up in front and above The anterior and internal walls were very thick, while the outer and posterior

walls were formed by the body structures The sac contained nearly three quarts of clotted blood and a great deal of laminated clot There was erosion of the bodies of the first, second, and third lumbar vertebrae The opening from the aorta was clear-cut, measuring one and one-half inches across and came from the aorta behind and slightly above the left renal artery Sections of the aorta in this region showed slight fibrosis, but the remainder of the vessel was comparatively healthy

These cases are not very common Out of 18,000 autopsies at Guy's Hospital, there were 54 cases, and in 19,300 autopsies in Vienna, the condition occurred but three times

L J CARTER, MD

Further Observations on the Operability of Gastric Cancer from the Radiologic Point of View Alberto Anzilotti Minerva Med, May 26, 1931, XXII, 804-807

If the radiologic examination of a patient suffering from cancer of the stomach is to give a criterion of operability, it must furnish exact indications of the size and location of the tumor, of the conditions of the remaining parts of the stomach, and of the extent of the probable diffusion of neoplastic process to the surrounding organs The author thinks that up to the present time radiologic investigation is diagnostically helpful but not entirely sufficient

He reviews 148 cases of carcinoma of the stomach diagnosed during the last three years Although 35 of them were judged operable, only 21 were operated upon on account of poor general condition and the presence of other diseases Furthermore, in seven instances the surgeon had to limit himself to exploratory laparotomy, radiologic findings having failed to include metastatic involvement of hopeless extension Gastro-enterostomy was performed in fifteen additional cases as a palliative effort in relieving stenotic ectasia

The author reviews the radiologic signs leading to the diagnosis of cancer of the stomach, he agrees with Haudek upon the operability of the cancerous stomach which has preserved its hooked shape, and insists upon the importance of the study of the gastric

able one to make a diagnosis without laboratory tests, and will almost always attract our attention to this organ when not sufficient to convict it of harboring disease.

The physical examination may reveal much or little. In most cases the history and physical signs are sufficient on which to make a diagnosis.

Cholecystography is a test of function rather than an estimation of disease. The functions of the gall bladder of which this test is an estimate are the ability to receive bile from the liver by way of the cystic duct, to concentrate and absorb it, and to empty it. The accuracy of the method is estimated at from 89 to 94 per cent. It would appear that cholecystography, although useful, has its limitations, and should be used as an assistant method in the diagnosis of cholelithic disease where symptoms are not definite and the diagnosis is obscure. This is often the case in chronic cholecystitis without stone.

Blood chemistry is important. The estimation of blood bilirubin is just as important in certain cases of cholelithic disease as a blood sugar test is in pancreatic disease. Frequent records of the van den Bergh test, kept graphically, will reveal a bilirubin curve. In a rising curve, the danger from hemorrhage, in the case of operation, is indicated. A falling curve indicates greater safety in operation, the danger of hemorrhage being lessened.

In 281 cases, 270 were found to be pathologic from X-ray findings, 36 of these showed stones prior to dye, 67 showed stones after dye. At operation, 268 of the cases showed

fell into two classes—the secondary and the primary. Most of them belong to the latter class, in which the route of infection is most difficult or impossible to trace. Fifty cases have been reported of the secondary type, following such lesions as malignant or peptic ulcers, infected operation wounds in the stomach, or abscesses in adjacent tissues or organs.

The prognosis is extremely grave. Of all untreated cases, 92 per cent end fatally. In the three hospitals in which the authors' cases occurred, there are none on record, except those which came to autopsy.

Surgical treatment may cure some of the more accentuated cases. The operation is gastrostomy, gastro-enterostomy, jejunostomy, resection, or drainage of abscesses.

L J CARTER, M D

Acute Intestinal Obstruction, with Report of Cases (Mechanical Type) J A William Johnson *Jour Am Institute Homeop*, November, 1931, XXIV, 1138-1142

Acute intestinal obstruction may be external, internal, acquired, congenital, or traumatic. Internal obstruction occurs within the peritoneal cavity, and can be located only after opening the abdomen. External obstruction is most commonly exemplified by external hernia. Foster and Hausler maintain that there are two types of obstruction: acute simple obstruction and acute strangulation.

It is commonly accepted that the toxic element in bowel obstruction has its origin in protein decomposition in the bowel. Gatch, Trusler, and Ayers have shown that the toxic elements are caused by the bacterial action on the obstructed loop and are not absorbed by normal mucous membrane, but only after tissue necrosis occurs. Haden and Orr have further pointed out the loss of chlorides and the rise in non-protein nitrogen of the blood that occur in intestinal obstruction.

The early diagnosis of intestinal obstruction is of the greatest importance and, unfortunately, the symptoms are often recognized too late by the attending physician to be of any use in surgical treatment. The most dependable symptoms are as follows: vomiting, colicky or cramp-like pains visible, palpable,

or audible peristalsis, inability to expel gas and feces, and absence of temperature. The meteorism increases as the obstruction becomes lower, and vomiting increases as the obstruction becomes higher in the intestinal tract. Acute intestinal obstruction always begins with pain and is always followed by vomiting of pathognomonic character. According to Sampson Handley, fecal vomiting should be considered as a sign of impending death rather than a sign of obstruction.

The author believes that the early use of the X-ray will help reduce the high mortality in intestinal obstruction. Roentgen examination will give the characteristic reticulated appearance of the shadow cast by the gas-distended small bowel in cases of acute obstruction. A barium enema in this type of case will do no harm and will serve as a valuable aid in diagnosis.

In treating these cases it is commonly accepted that relief of the obstruction by surgical means is the first and most important consideration. The administration of sodium chloride by hypodermoclysis or by vein is essential, even before any operation is undertaken. This treatment makes a better operative risk and should be kept up post-operatively until the patient is out of danger. It is wise, likewise, to begin the intravenous administration of glucose early and continue until the patient can take food by mouth. The author includes several case reports of obstruction of different varieties.

J N ANÉ, M D

The Relationship of Disorders of the Digestive Tract to Anemia William B Castle, Clark W Heath, Maurice B Strauss, and Wilmot C Townsend *Jour Am Med Assn*, Sept 26, 1931, XCVII, 904-907

Anemia can presumably be produced either by an excessive loss or destruction of blood in the presence of a normally acting marrow, by a failure of the marrow to produce normal red blood cells in quality or quantity, or by a combination of these two factors.

If the food is to affect the bone marrow in some way, it is obvious that it must be absorbed from the gastro-intestinal tract. In

rugæ in the determination of the size of the lesion He mentions two cases personally observed and surgically confirmed in which a total spasm of the antrum, due respectively to superficial ulcer and chronic gastritis, led to the hypothesis of epithelioma, which was discarded later because a careful study of the rugæ revealed the presence of spastic process The difficulties encountered in the diagnosis of hepatic metastasis are pointed out by the author, who also states that one of the differential signs between ulcer and cancerous stenosis is to be found very often in the mechanism of digestion

L MARINELLI

Epigastric Hernia of the Stomach Osvaldo F Mazzini and Domingo Brachetto-Brian La Semana Méd, Sept. 10, 1931, XXXVIII, 807-809

Since epigastric gastroceles are so rare that only one case has been reported in the literature, the authors present such a case in which the diagnosis was made both clinically and radiologically

The hernia of this case was of eight years' duration and the size of a Brazil nut It was symptomless The lateral radiograph showed the gastrocele beautifully The patient was operated on and hernioplasty performed

N G GONZALEZ, MD

Phlegmonous Gastritis, with a Report of Four Cases J E Pritchard and J W McRoberts Canadian Med Assn Jour, August, 1931, XXV, 183-187

Within the last three years four cases of phlegmonous gastritis have been met with in the postmortem services of the Montreal General, the Royal Victoria, and the Notre Dame Hospitals of Montreal

The first case, a male, aged 19 years, had severe cramp-like pains in the epigastrium, immediately followed by vomiting The tentative diagnosis was perforated peptic ulcer At operation a thick greenish purulent fluid was seen to flow from the subhepatic region, a culture of which revealed hemolytic streptococci At autopsy the stomach was large and dark reddish-brown in color There were nu-

merous subperitoneal hemorrhages over the whole surface, most marked along the greater curvature The wall throughout was boggy, edematous, and markedly thickened The mucosa was covered with grayish, turbid fluid, containing fine granular suspensions The normal rugæ of the mucosa had disappeared and were replaced from the cardia to the pylorus by deep longitudinal troughs Microscopic sections proved that the thickening of the wall was mostly the result of a marked edematous swelling of the submucosa. Scattered diffusely throughout and extending between the bundles of the muscular coat were abundant leukocytes (pus) The mucosa was relatively well preserved, with a much slighter infiltration of leukocytes Sections through the pylorus showed a much more advanced involvement of the submucosa and muscular coats by the leukocytes, with necrotic fusion resembling an abscess The anatomic diagnosis was phlegmonous gastritis, with exudative purulent peritonitis

Cases 2, 3, and 4 were all discovered at autopsy The anatomic and microscopic findings were the same as in the first case Smears from the stomach wall and from the exudate showed abundant streptococci in all of them

The authors review the literature of this condition Although nearly always fatal, there have been some cases of phlegmonous gastritis cured by surgical treatment The disease, therefore, occasionally presents a diagnostic problem of importance It is a rare condition and is not often diagnosed before the abdomen is opened

In 1919, Sundberg reviewed 215 cases Gerster, in 1927, collected 48 additional cases Since 1927, some 22 additional cases have appeared in the literature

Of the four cases reported by the authors, one was the second case encountered in 4,188 autopsies at the Royal Victoria Hospital in the past twenty years At the Montreal General Hospital there have been observed four cases, including 2 and 3 of this series, among 9,300 autopsies in the past thirty-four years Case 4 is the only one on record at Notre Dame Hospital

Concerning the mode of infection, the cases

cholecystostomy, although primarily an operation of necessity, is nevertheless also valuable in cases susceptible to treatment (chronic cephalo-pancreatitis, for example), provided that they fulfill the requirements of a small stoma, and are permeable and as continent as possible, as shown by the radiographs in two of the observations. A large stoma, as seen in one of the observations, may give rise to dilatations by way of the biliary channels, with the danger of retrograde infection of the same.

From this it follows, other things being equal, and given the greater septic content which forms gradually in anastomosis with the involved segments of the intestine, that cholecystostomy offers a greater guaranty of sterility and from this point of view shows its superiority to other procedures.

W W WHITELOCK, Ph D

A Case of Ileo-ceco-colic Invagination
Guido Piccinino Archivio di Radiologia,
May-June, 1931, VII, 480-489

The author reports a case in which there were present all the radiological signs of ileoceco-colic invagination, which he gives in detail. At operation there was found no invagination but an adenocarcinoma of the cecum. He advises great caution in elaborating theories of the causation of this lesion, and, in making a diagnosis of it, he advises examination with barium given by mouth and by enema in order to eliminate the possibility that a tumor causes the invagination.

E T LEDDY, M D

Improved Method for Roentgen Examination of the Colon P C Schnoebelen Jour Mo Med Assn, November, 1931, XXVIII, 539, 540

This method consists of the introduction of 8 ounces of barium sulphate suspension into the rectum, the first film being made in five minutes. After part of the injected solution is expelled, a second film is made. Then all of the suspension possible is expelled and a third film made. Normal behavior is for all the barium suspension to remain in the pouch for the first film and to be entirely expelled

as shown by the third film. Rectal constipation is inability to empty the pouch. If the barium leaves the pouch and passes through the sigmoid, abnormality is present. The barium will ascend to an obstruction and outline its distal surface, it will also outline the narrowed canal of a partial obstruction. The fluoroscopic examination is made and correlated with the film findings.

**GENITO-URINARY TRACT
(DIAGNOSIS)**

Congenital Bilateral Uretero-vesical Junction Stricture in Infants and Children
Meredith F Campbell Jour Urol, October, 1931, XXVI, 529-546

Congenital ureteral strictures occur in approximately 1 per cent of all individuals, are found most often at the uretero-vesical or uretero-pelvic junctions, and may be multiple as well as bilateral. When stricture is bilateral, the ultimate development of bilateral renal infection is inevitable and this, together with the symptoms caused by renal insufficiency, constitutes the clinical picture. This article is concerned only with bilateral congenital uretero-vesical junction stricture. The diagnosis is easily made by urologic examination. While removal of the obstruction is the usual indicated treatment, occasionally nephrectomy is demanded. The author reports on fifteen cases of this lesion. The ages of the clinical cases vary from two months to eleven years, the four autopsy cases included ranged from stillbirth to six months.

The embryologic etiology of congenital ureteral stricture is unknown. Apparently the incidence is higher in females. The micropathology of the stricture varies depending upon the amount of fibrous tissue and the presence or absence of inflammation. There is no evidence to indicate that localized muscular hypertrophy is the cause of the ureteral atresia in these cases. The changes in the upper urinary tract are quite the same, irrespective of the character of the ureteral blockade. The ureters and pelvis are dilated, bilateral hy-

general, it can be shown that patients with diarrhea are more prone to develop anemia than patients without diarrhea. Liver extract administered by daily intramuscular injection to patients with pernicious anemia is many times as effective as when given by mouth. This may indicate that difficulty with the assimilation of hematopoietic substances from the gastro-intestinal tract has a bearing on the etiology of pernicious anemia.

Pernicious anemia is a deficiency disease, resulting not from a direct inadequacy of the diet but from a conditioned deficiency produced by the failure of some function of the normal stomach to take place in the stomach of a patient with pernicious anemia. This reaction in normal individuals, they believe, has to do with the manipulation of protein and leads to the absorption of a factor necessary for the maintenance of normal bone-marrow activity. In general, disturbances of the gastro-intestinal tract of various kinds may interfere with absorption or with processes necessary for the proper metabolism of food substances essential for the normal functioning of bone marrow. In this way, even in the presence of a normal diet, disturbances of the digestive tract may condition a deficiency of nutrition, in particular of substances essential for blood formation.

C G SUTHERLAND, M B (Tor)

The "Common Mesentery" from the Surgical Point of View A Zaffagnini L'Ateneo Parmense (Suppl), 1931, III, 59-83

We may speak of a "common mesentery" whenever in the living subject there is encountered a doubling of the parietal peritoneum, common to the small and to the proximate portions of the great intestine, and which, permitting excessive mobility to the latter, is associated in greater or lesser degree with abnormal rotation.

Thus defined, a common mesentery is a fairly rare anomaly and one which shows no predilection as regards the sexes. In the radiologic picture of the anomaly, as gathered from the examinations which have been made, the stomach, which is normally placed, is fol-

lowed by the duodenum, which at times has a normal aspect, course, and fixity, but which more often is mobile and situated to the right of the median line. The small intestine is entirely dislocated in the right half of the abdomen and maintains this condition no matter what position the patient is made to assume. The ileac loop, running from right to left, enters the cecum, is generally very mobile and also very low, approximately behind the pubis. The colon is a twisted mass in the right half of the abdomen, and while the splenic angle, the descending colon, and sigma are in place, the ascending and transverse segments show numerous convolutions in the left half of the abdominal cavity, giving thus the impression of an abnormally long distention of the transverse. All the portions of the colon in front of the splenic angle are very mobile, so that the enema in distending the colon may expel portions of it into the half of the abdomen.

The author studied five cases of common mesentery, clinically and radiologically, only one of which came to operation, with a doubtful diagnosis fluctuating between appendicitis and peritoneal tuberculosis. Knowledge of the condition, he concludes, is of genuine importance to the surgeon, not only because of the complications to which it may give rise (volvulus, invagination, etc.), but also because of the morbid conditions frequently associated with it (appendicitis, cholecystitis, gastroduodenal ulcer, etc.). These conditions, due to the presence of the congenital malformation, assume a graver course, probably because the latter creates a *locus minoris resistentiae*.

W W WHITELOCK, Ph D

Enterobiliary Anastomosis, with Special Reference to Cholecystostomy A Zaffagnini L'Ateneo Parmense (Suppl), 1931, III, 324-355

After passing in review the various experimental stages through which the problem of enterobiliary anastomosis has passed, especially as regards cholecystostomy, the author reports five cases which were subjected to this operation. There was radiologic control of three of the cases not less than twenty months after operation. He concludes that

heavy load on the kidneys. The urine remains normal and the kidneys of laboratory animals do not show any pathologic lesions other than at times a slight cloudy swelling. The iodine content of skiodan is high, 52 per cent, but the iodine is in firm combination and is not set free in the urine.

Little preliminary preparation of the patient is necessary. A good cathartic is given the night before, followed by an enema in the morning. Twenty or twenty-five grams of the drug are dissolved in 100 c.c. of double distilled water. The solution is then filtered twice and is sterilized in an autoclave for 20 minutes at 15 pounds pressure. The solution is then cooled to body temperature and is injected into the median cephalic or basilic vein. There have not been any general reactions whatsoever, and, provided that all the solution went into the vein, there were no local reactions.

The first film is taken ten minutes after the injection, and one every 15 minutes for the next hour. From then on, films are taken depending on the excretion of the drug.

The only contra-indication to the use of the drug is severe impairment of the function of the kidneys.

A number of excellent reproductions of films showing such conditions as hydronephrosis, hydro-ureter, destroyed kidney, accompany the contribution of the authors.

L J CARTER, M D

Roentgen Diagnosis in Intravenous Pyelography Jesse J Peters Med Bull Veterans' Administration, October, 1931, VII, 918-921

The author reviews the history of intravenous pyelography and discusses the preparation and use of uroselectan in the study of pathologic conditions of the urinary tract. Intravenous pyelography offers a simple, painless method of examining the kidney pelvis, ureters, and bladder, radiographically producing urographs of diagnostic quality. This method does not replace retrograde pyelography, but should serve as an aid to determine function in surgical kidneys. In those cases, however, in which cystoscopy is difficult or impossible the intravenous method will be found most useful.

It offers valuable aid to the following, heretofore denied this important diagnostic aid: (1) Infants and children, (2) debilitated adults, (3) urethral stricture cases, (4) cases with deformities, (5) certain malignant cases. It is the method of choice in the absence of a competent urologist.

Hydronephrosis is probably the most commonly met pathologic change in the kidney. In those cases a careful study of the urographic findings should be made. Mechanical obstruction high in the ureter shows the pelvis greatly enlarged, with a flattening of the renal papillæ. On the other hand, obstructions lower in the ureter dilate the ureter and pelvis but very frequently do not involve the minor calices. Dilatations due to infections are generally less extensive than those of a purely mechanical nature and are more prone to distortions and irregularities in contour, due to the reaction of the renal epithelium.

J N ANÉ, M D

Ureterography in Some Blennorrhagic Sequelæ and in "False Passages" L Brunetti. Archivio di Radiologia, May-June, 1931, VII, 445-465

The author reports some ureterographic studies in a score of patients with sequelæ of gonorrhea. In his discussion of the normal and pathologic anatomy of the urethra, he advances some of his own views on the value of X-ray examination of it. In two cases of traumatic false passage he demonstrated its location and extent by injection of lithium iodide. An extensive bibliography on radiography of the urethra is appended.

E T LEDDY, M D

Cortical Adrenal Tumor Hunter, McMillan, Boyd, and Cameron Canadian Med Assn Jour, August, 1931, XXV, 188-193

Hunter reported, at a clinical conference, the case of a female, aged 30, admitted to the Winnipeg General Hospital, complaining of weakness, loss of weight, pain in the back, amenorrhea, shortness of breath, and swelling of the feet and legs. She had been a patient in the outdoor department about a year and a

dronephrosis may be extreme. The parenchyma shows compression nephritis and, usually, infection. If the child lives, urinary infection eventually occurs in all these cases. With the advent of infection, the upper tract pathologic process is intensified, and with advancing bilateral renal damage the signs and symptoms of uremia or urinary sepsis occur.

The late results of urinary back pressure plus infection are found in the elongated, angulated, tortuous, atonic, scarred ureters and in the thinned, sclerosed, and infiltrated renal tissue.

The clinical picture is the summation of symptoms due to infection and obstruction. Of the objective symptoms, persistent pyuria and the indication for urologic examination are outstanding.

Commonly accompanying pyuria are gastrointestinal upsets, low-grade fever, anemia, malaise, loss of weight or failure to gain, and pain due to the hydronephrotic distention. Secondary symptoms due to inflammation of the vesical outlet may be present. Marked diminution of renal function presents the usual train of uremic symptoms.

Urologic examination should include urinalysis, blood chemistry, two-hour phenolsulfonphthalein test, plain roentgenogram of the urinary tract, cystogram, cystoscopy, ureteral catheterization, divided renal function tests and, usually, pyelography.

In bilateral ureteral vesical junction stricture two findings are characteristic: (1) Difficulty in or impossibility of passing No. 4 F catheter into the ureters until the second or third examination. Upon withdrawing the catheter there is tightening of the ureter and a grasping of the catheter similar to that which occurs in urethral stricture upon the passage of a sound. Having introduced the catheter, a steady ureteral drip, characteristic of hydronephrosis, is obtained. (2) The pyelogram reveals a dilated ureter beginning in the strictured area and terminating in a hydronephrotic renal pelvis. Intravenous pyelography has not served as efficiently as the retrograde method in this type of cases.

Eradication of the obstruction is the treatment. In six of the patients gradual catheter dilatation was utilized. In the author's ex-

perience these strictures recontract rather rapidly. While marked diminution in pyuria and infection have consistently followed this treatment, in no instance has there been a bacteriologic cure.

Failing to obtain satisfactory dilatation by cystoscopic methods, open operation (transvesical ureteral meatotomy and stricture section) may be resorted to. In extremely ill patients with low renal function, preliminary bilateral ureterostomy drainage is indicated, followed by the necessary surgical measures after the renal function has been sufficiently restored. Unilateral renal damage and infection may be so extensive as to require nephrectomy. Occasionally resection and transplantation of the dilated atonic ureter may be necessary, although this is productive of ureteral regurgitation.

This study serves to re-emphasize the importance of complete urologic examination in children when pyuria—usually diagnosed as chronic pyelitis—exists. While operative treatment cannot always offer a complete cure, surgical results exceed those obtained by any other method. Medical therapy alone is inadequate, with continued back-pressure, renal destruction and uremic death may be anticipated.

A liberal number of roentgenograms and illustrations of this pathologic condition accompany the article.

DAVIS H. PARDOLL, M.D.

Intravenous Pyelography with Skiodan A Brief Clinical Report David W. MacKenzie and Max Ratner Canadian Med Assn Jour, August, 1931, XXV, 172-174

The introduction of uroselectan for intravenous pyelography by Swick and von Lichtenberg has proved to be an invaluable aid in the diagnosis of genito-urinary disease. The drug is a popular one and is being used extensively all over the world. Since April, 1931, the authors have been using a new drug, skiodan, which has proven a safe and reliable medium.

The drug is a very efficient diuretic and the rate of excretion is high. In spite of this rapid excretion the drug does not throw a

vesicles, vasa, right kidney, lungs, fifth lumbar vertebra, and lymph nodes. The third was a squamous-cell carcinoma of the cervix which metastasized to the right ureter, liver, and mesenteric lymph glands. In 1927, Carson reported two additional cases. The first was a carcinoma of the prostate which metastasized to the right ureter, bladder, seminal vesicles, lumbar vertebræ, and mesenteric lymph nodes. The second was a carcinoma of the prostate which metastasized to the right ureter, bladder, seminal vesicles, right kidney, pelvis, lungs, and lymph nodes.

Rathbun, in 1929, described a single case. The patient, a male, had metastasis in the left ureter, secondary to scirrhous carcinoma of the left breast, which had been removed three years previously.

The authors carefully reviewed all the cases with lesions of the ureter that have been met with in the Departments of Urology and Pathology at the Royal Victoria Hospital, Montreal. They found three cases of metastatic growths, thus making a total of eleven authentic cases.

Of the three cases found, one was in a female and two in males. The female was 34 years of age, and the males 45 and 61. Both the male cases came to autopsy, and the diagnosis was made on the postmortem table. The female patient is still alive. The diagnosis in her case was made at operation. The first patient came into the hospital complaining of shortness of breath, palpitation, swelling of the legs, cough, bloody expectoration, and slight nocturnal urinary frequency. The symptoms had been of one year's duration. The clinical diagnosis was chronic nephritis, aortitis, and chronic myocarditis, with decompensation. The patient died 48 hours after admission to the hospital. The postmortem findings were adenocarcinoma of the prostate, with metastases in the ureters, lungs, and lymph glands, bilateral hydronephrosis, hypertrophy of the heart, arteriosclerosis, dilatation of the first part of the aorta. Although the patient died from carcinoma of the prostate, with multiple metastases, yet the clinical picture was that of cardiac failure and renal insufficiency.

The second case was one of carcinoma of the stomach. There were no symptoms referable to the urinary tract, yet the postmortem examination revealed metastatic growths in the right ureter.

The third case was discovered on the operating table. A carcinoma of the cervix had been treated by radium a year previously, with apparently good results. One year after treatment the patient began to complain of severe pain in the left loin, radiating down and forward, frequency of urination, anorexia, and loss of weight. A clinical diagnosis was made of an obstructed ureter, with a left hydro-nephrosis. The patient was operated upon and a nephrectomy and partial left ureterectomy were done. The anatomical diagnosis was carcinoma of the ureter secondary to carcinoma of the cervix.

In summarizing their contribution, the authors note that the diagnosis of a newgrowth of the ureter, whether primary or secondary, is made almost always at operation or on the autopsy table. There are no signs or symptoms which are pathognomonic, and the condition is rarely considered. The outstanding symptom is pain. This may be represented by a dull steady ache on one or the other side, or may simulate a severe renal or ureteral colic. Hematuria is a variable symptom. In primary growths it occurs at one time or another during the course of the disease, and may be profuse or very scanty. In metastatic growths, on the other hand, hematuria will not occur unless the growth has encroached on the lumen of the ureter. Frequency, urgency, and dysuria are occasionally complained of, and usually result from a secondary infected hydronephrosis and hydro-ureter. Cystoscopy gives the most information.

L J CARTER, M.D.

Foreign Body in the Abdomen as a Result of Attempt at Abortion Localized by X-ray
Dino Agati Archivio di Radiologia, May-June, 1931, VII, 466-472

This is a case report of attempted abortion by means of a catheter introduced into the uterus. The uterine wall was ruptured, and there was found on X-ray examination an

half previously, when a tentative diagnosis of chronic glomerular nephritis was made

He indicates that the diagnosis should be obvious from a study of the clinical history and an ordinary physical examination. This is emphasized in view of the modern tendency to substitute laboratory diagnosis for the safer but more time-consuming bed-side examination. When menstruation disappears, when hair of the masculine type of distribution develops profusely in a young woman of buffalo-like disproportion of shoulder and buttock, who exhibits a large tumor in the renal region and a hypertrophied clitoris, tumor of the adrenal cortex is the probable diagnosis.

McMillan gave the X-ray findings as follows. The right diaphragm is elevated, being one and one-half interspaces higher than the left. It has the normal curve, which would suggest that the displacement is due to some intra-abdominal pressure. There is a clear-cut, circular, opaque area in the lower part of the right chest, just above the diaphragm, which has very much the appearance of a metastatic lesion from a malignant kidney. There is marked decalcification of the bodies of the last dorsal and all the lumbar vertebrae. The bodies of these vertebrae are more or less collapsed, the third being the least deformed. The left kidney shadow is distinctly seen, but the right is not. There is a small circular shadow superimposed on the ninth rib posteriorly, and well out from the midline. A pyelogram made on the right side shows the pelvis and calices to be well visualized. The kidney is apparently displaced downward and the upper pole rotated outward. The upper calyx shows some deformity.

Boyd reported on the pathologic examination of the tumor removed from the vaginal wall, which resembled tumors of the adrenal cortex.

Cameron discussed tumors of the adrenal cortex and their effect in producing the sex changes noted.

L J CARTER, M D

Max Ratner Canadian Med Assn Jour, September, 1931, XXV, 265-270

Pathologic lesions that are of rare occurrence, and usually diagnosed at the autopsy examination or in the operating room, always stimulate interest and discussion. Metastatic growths of the ureter belong to this class, and lately the authors encountered such a condition. They review the literature and collect other similar cases that have been met with at the Royal Victoria Hospital.

Newgrowths of the ureter, whether primary or metastatic, are extremely rare occurrences, the former appears to be the commoner of the two. Although only 59 cases of primary growths of the ureter are reported, yet an appreciable amount of literature has been written on the subject. On the other hand, very little has been published on metastatic growths of that organ. Up to December, 1930, only eight authentic cases could be found in the literature.

It is of extreme importance to emphasize that under the heading of metastatic growths of the ureter are included only those lesions that have been proved definitely to be the result of metastasis conveyed to the ureter by lymphatics or blood vessels. Secondary growths of the ureter, due to direct extension of tumors of adjacent organs, such as the uterus, bladder, or kidneys, are not true metastases, and are not included, therefore, in this class. Moreover, in order to prove that a secondary growth is a true metastatic one, malignant cells must be demonstrated in the perivascular lymphatic spaces or blood vessels of the ureter.

The first authentic case of a metastatic growth of the ureter was reported by Giordano and Bumpus, in 1922. This was a carcinoma of the prostate which had metastasized to the left ureter, left renal pelvis, lungs, and left kidney.

In 1925, Carson added three more cases to the literature. The first was that of a man with a carcinoma of the bladder which metastasized to both ureters, prostate, mesenteric lymph nodes, lumbar vertebrae, and liver. The second had an adenoma of the prostate with metastasis to the right ureter, bladder, seminal

done Examination of the removed kidney by the pathologist revealed nothing more than a slightly dilated pelvis, and a small scar in the cortex which suggested a healed inflammation The patient has been perfectly well ever since

Case 3 A woman of 57 was admitted suffering from attacks of pain in the left lower quadrant, associated with frequency of urination Cystoscopy showed a normal condition of the bladder and ureters The diagnosis was peritoneal adhesions, causing intermittent hydronephrosis and pyelonephritis A laparotomy was advised but the patient did not consent Six months later the patient returned with the condition unimproved Cystoscopy again was normal for urogram of the left kidney and ureter At operation the sigmoid was found adherent to the base of the broad ligament, posteriorly The lesions were removed and the uterus suspended to the anterior abdominal wall The ureter was palpated and appeared to be normal The patient has been perfectly well in the two years that have elapsed since the operation

L J CARTER, M D

Criteria of Interpretation and a Critical Evaluation of Intravenous Pyelography
Mario Luigi Asti Archivio di Radiologia, May-June, 1931, VII, 589-604

The author reports some studies carried out with uroselectan and abrodil He points out the safety and advantages of this examination, but feels that incorrect interpretation of the findings may lead to grave diagnostic errors He shows that ascending pyelography is still a method of the greatest importance

E T LEDDY, M D

A Case of Bilateral Hydronephrosis, Pyelonephritis, and Kinked Ureters, Treated by Bilateral Nephrostomy, Demonstrating the Recovery Phase in the Pathological Physiology of the Ureter Channing S Swan Urol and Cutan Rev, November, 1931, XXXV, 713-715

It has been demonstrated that as a result of partial obstruction of the ureter hypertrophy and hyperplasia of the musculature, elongation, tortuosity, and dilatation of the ureter de-

veloped A similar reaction is noted in pregnancy, as a result of pressure on the ureter by the enlarging uterus Crabtree demonstrated that in the average normal case the ureter returned to normal in three months postpartum Quinby stated further that mere infection of the ureter without pregnancy or obstruction would produce similar changes He also believed that the ureter would return to normal after the infection had been cleared up, if there was not too severe a degree of peri-ureteritis fixing the organ in its snake-like position From one to two years was considered the recovery time, as demonstrated by the X-ray

The author's patient, a woman 52 years of age, and the mother of thirteen children, complained of pain of six months' duration in the left kidney region When first seen she was vomiting, and there was tenderness and the question of a mass in the left kidney region A pyelo-ureterogram showed a kinked left ureter and a left hydronephrosis The temperature, pulse, and respirations were elevated The day after admission she complained of pain in the right kidney region Pyelography revealed a tortuous kinked ureter and a mild hydronephrosis on the right, similar, but less marked, to that on the left About one week subsequent to admission a left nephrostomy was performed under local anesthesia, twenty days later nephrostomy being done on the right kidney The right nephrostomy was permitted to heal in ten days, but the left side was kept open

Three months after her original entry she returned for observation Pyelo-ureterograms revealed normal ureters and practically normal renal pelvis The left nephrostomy was then allowed to heal Further observations showed complete recovery from the urologic condition The author believes that this case demonstrates the power of the ureter to recover anatomically and physiologically from the elongation and tortuosities which come with infection

J N ANE, M D

The Radiologic Findings in Cystic Dilatation of the Lower End of the Ureter as

opaque catheter—a Gregory No 10—lying almost completely inside the peritoneal cavity. Following laparotomy and removal of the foreign body, the patient made a smooth convalescence. The author emphasizes the importance of X-ray examination in cases with obscure objective signs and subjective symptoms, as in this patient.

E T LEDDY, M D

The Effect of Peritoneal Adhesions upon the Urinary Tract Frank S Patch and Merle D Evans Canadian Med Assn Jour, October, 1931, XXV, 399-401

Obstructions of any part of the urinary tract by lesions outside it constitute an interesting chapter in urology. Examples of this are constantly to be found in connection with the genital organs of the female, as displacements and tumors of the uterus, inflammatory deposits in the parametrium affecting the bladder, and, in both sexes, malignant metastatic growths in the pelvis, profoundly affecting the ureters and kidneys. Urologic textbooks only occasionally deal with this type of lesion. We have not observed any reference to the effect of peritoneal adhesions in producing ureteral obstruction. It appears to us, however, that the lesion is much more common than this would indicate, and that the possibility of its occurrence should be borne in mind by urologists in cases of hydronephrosis in which no other etiologic factor can be found. Three cases of this sort have been observed in the urologic service of the Montreal General Hospital, and are here reported in detail.

The three cases differ markedly in various respects. The first was an accidental autopsy finding which furnished definite proof that the lesion produced almost complete destruction of the kidney above the obstruction. The other cases were clinical observations, with markedly contrasted therapy, in one case radical, in the other conservative.

Case 1 A married woman, aged 67, was admitted with a history of frequency of micturition and incontinence of urine. She was found to have residual urine of 2,230 cubic centimeters. The specific gravity of the urine was 1,020, reaction alkaline, and it contained

albumin, pus, and red blood cells. X-ray examination of the genito-urinary tract was negative. Cystoscopy showed the capacity of the bladder to be reduced. The bladder wall was friable and covered with an adherent slough, gangrenous in character. The ureteral orifices could not be seen. Cystostomy was done and drainage was effected by a Freyer tube. There was slight temporary improvement, followed by a lapse into unconsciousness and death. Autopsy showed a gangrenous cystitis. The left ureter and kidney were normal, the right ureter and kidney were greatly dilated and filled with a dark foul-smelling material. The kidney cortex was much inflamed. The point of interest, and the one accounting for the right pyo-ureter and right pyo-nephrosis, was found in several pelvic adhesions, one of which ran from the postero-lateral border of the right broad ligament to the peritoneum just beyond the sacro-iliac synchondrosis. This band crossed the ureter close to the bladder and tightly compressed it, leaving a distinct furrow below which the ureter was of normal caliber, immediately above it the ureter was widely dilated.

Case 2 A man aged 54 had suffered repeated attacks of pain in the left lower quadrant of the abdomen. These attacks had been present off and on since an abdominal operation in 1919, for a supposed abdominal tumor. In 1923, the abdomen was opened for adhesions, but without relief. The pains were colicky in nature and accompanied by nausea and a desire to urinate, which act gave relief. Cystoscopy showed a smaller left ureteral orifice, and there was a suggestion of ureteral narrowing but no hydronephrosis. The ureter was dilated to No 11 Fr on several occasions, without relief. The abdomen was opened and numerous adhesions in the left lower quadrant were separated with difficulty. The patient remained well for a year, when the pains again returned. Pyelography showed a normal kidney. The abdomen was again opened and dense adhesions between the bowels, the pelvic walls, and the bladder were found impossible of removal. The attacks continuing, it was seen that nothing could be done but remove the apparently normal left kidney. This was

used, the author takes great pains in this article to describe the technical points which must be followed in order to obtain good results. He presents two cases of dilatation of the pelvis and ureters, due to pressure (pregnancy) in which resort was had to intravenous pyelography.

N G GONZALEZ, M D

Renal Carbuncle Albert R Fritz and Leo S Drexler Urol and Cutan Rev, November, 1931, XXXV, 703-705

Carbuncle of the kidney, described by Israel, in 1901, is considered rather rare, as a recent review of the literature by Moore revealed only 42 cases. The authors report an additional case and discuss the etiology, pathology, symptomatology, diagnosis, and treatment of renal carbuncle.

The patient, a boy, 18 years of age, complaining of pain in the right lumbar region associated with fever and general malaise, was admitted for hospitalization. His urine was persistently negative for pus or blood, and there were no urinary symptoms. History disclosed that the patient had been annoyed by pimples over his neck and back, which had subsided six weeks before the onset of the present illness. Physical examination revealed an acutely ill, emaciated individual, whose temperature was 99.2, pulse 86, and respiration 20. The abdomen was somewhat distended, but no masses were palpable. Cystoscopic examination was negative except for slight obstruction to the ureteral catheter high up on the right. Indigo carmine, injected intravenously, returned in three minutes on the left and in seven minutes on the right. Roentgenologic examination showed an enlarged right kidney. Pyelography revealed a moderate degree of pyelectasis on the right. The upper calyx was elongated and a large cystic dilatation, apparently communicating with the inferior major calyx, was noted and filled with the injected sodium iodide. The culture of urine from the right kidney was reported as *B. coli*. The blood examination showed 26,600 leukocytes, with 80 per cent polymorphonuclear cells. A diagnosis of renal carbuncle was made from the history and roent-

genologic findings, and the patient was operated on. The abscess was found well walled off, of considerable size, and bearing the typical appearance of a carbuncle as met with in other portions of the body. Nephrectomy was performed and the patient's convalescence was uneventful.

This condition was found to attack men more frequently than women, and the age limits in the reported cases range from 10 to 55 years. The original focus of the *Staphylococcus aureus*, the usual invader, is often considered trivial. Trauma is believed to be an important predisposing factor. The pathologic picture is usually confined to the cortex, although in some cases it may rupture into the capsule and produce a perinephritic abscess, or, rarely, it may involve the remainder of the kidney and drain through the pelvis and the ureter.

The onset is usually insidious with malaise, loss of appetite, and an intermittent fever. Leukocytosis, with counts from 10,000 to 25,000, is the rule. Pain, nausea, and vomiting are also encountered in some cases. The authors believe that the history of the case is the most important factor in the diagnosis. However, differentiation from an acute embolic metastatic kidney is difficult. Deformities in the renal pelvis and distention of the calices, as observed by pyelography, have been reported by Moore, Dick, and Horn. The distention of the pelvis, due to the pressure of the abscess, often suggests a renal neoplasm.

In the treatment of renal carbuncle, nephrectomy is believed to be the treatment of choice. In cases in which the carbuncle is small, resection has been recommended. Moore reported a case in which complete cure was obtained by the intravenous administration of mercurochrome.

J N ANÉ, M D

The Lateral Pyelogram A Neglected Procedure in the Diagnosis of Various Abdominal Conditions H O Mertz Jour Indiana St Med Assn, October 15, 1931, XXIV, 537-541

The technic of making a lateral pyelogram should be studied and worked out by each

Shown by Descending Pyelography Guerino Lenarduzzi Archivio di Radiologia, May-June, 1931, VII, 580-588

The author thinks that descending pyelography gives a complete pathognomonic picture of cystic dilatation of the ureter, because it gives natural filling of both the ureter and the bladder and so brings to light the real morphology of the two organs. Therefore, descending pyelography is superior to ascending pyelography in the study of this lesion.

E T LEDDY, M D

Traumatic Rupture of the Urinary Bladder Due to Fracture of the Pelvis Joseph A Lazarus Urol and Cutan Rev, December, 1931, XXXV, 761-764

Traumatic rupture of the urinary bladder results more frequently from external violence than internal forces, but both types of injury may serve as etiologic agents. Intra-peritoneal ruptures are more frequently encountered than the extra-peritoneal types. Since the traumatic force is most frequently directed to the lower abdominal wall, the rupture usually occurs in the upper median part of the bladder surface, a portion of the bladder usually covered by peritoneum. The entire thickness of the vesical wall is usually involved in a laceration of this viscus.

Extravasation of urine and infection are the most important complications of rupture of the urinary bladder. Hemorrhage rarely occurs and, when present, is not sufficient to endanger the life of the patient. In the intra-peritoneal type of rupture the results attending the extravasation depend mostly upon the character of the urine. Sterile urine leads to peritoneal irritation and peritonitis as a late complication. Diffuse peritonitis is generally the rule in cases of intra-peritoneal rupture of an infected bladder. In cases of extra-peritoneal rupture, the tissues affected by the extravasation depend directly upon the position of the laceration. Cellulitis, with abscess formation, may result from superimposed infection of the extravasated urine.

Immediately following rupture of the bladder the patient is usually in shock. Pain, tenderness, hematuria, toxemia, and inability to void are characteristic symptoms in all cases.

of vesical laceration. Pain is present in all cases, accompanied by vomiting and distention in those cases in which the extravasation is intra-peritoneal. Fever occurs with the onset of infection. In untreated cases intoxication results from absorption and infection, frequently terminating in uremia and death.

In some cases the diagnosis may be made from the history alone. Vaughn and Rudnick advise the injection of a small amount of air into the bladder while the patient is under the fluoroscope. The association of rupture of the bladder and fracture of the pelvis is always serious because of the possibility of osteomyelitis.

The treatment of rupture of the urinary bladder is always surgical and consists of the eradication of the sinus tracts and repair of the rent itself. The average mortality resulting from surgical treatment of intra-peritoneal rupture of the bladder, as compiled by Young, from various clinics, is 51 per cent.

The author presents the case of a female child, two and one-half years old, who presented a fistulous urinary tract opening on the upper and inner aspect of the right thigh. There was likewise a free escape of urine through the vagina. Six months previously the patient had sustained a fracture of the pelvis as the result of an accident. At the time of examination by the author, a cystogram, taken after the injection of opaque medium through the sinus of the right thigh, outlined the fistulous tract extending along the right pubic bone into the bladder. The bladder appeared thickened and trabeculated. At operation the bladder wall was found greatly thickened and the vesical cavity contained a large quantity of necrotic and calcareous material. After surgical treatment the patient made an uneventful recovery.

J N ANÉ, M D

Pyelography by Descending Route Carlos Heuser La Semana Méd, Sept 10, 1931, XXXVIII, 851-855

Since many reports have come out in the literature concerning poor results obtained from intravenous pyelography, particularly in cases in which uroselectan and abrodil are

portance of congenital strictures of the ureter should be remembered also

Ureteral conditions may give rise to many symptoms in organs quite unrelated to the genito-urinary tract. A number of patients, especially women, have persistent and obscure gastro-intestinal symptoms with negative gastric analyses. Many of these patients are operated upon for various gastro-intestinal conditions, and experience no relief after the operation. Usually after considerable study, evidences of hydronephrosis are found, and the patients find themselves free of symptoms after dilatation of the involved ureter.

While the majority of ureteral calculi have their origin in the kidney, the author believes that constriction and obstruction of the ureter offer very favorable conditions for the production of calculi directly at the site of the lesion. Ureteral fibrosis may precede or cause the stone, or may be extended by a stone descending from the kidneys, and arrested by a pre-existing soft stricture.

The author concludes that all vague abdominal pain, gastro-intestinal symptoms, and obstinate backache should be carefully considered and studied by the internist, the pathologist, the roentgenologist and the urologist all working together in mutual co-operation.

J N ANÉ, M D

Hydrosalpinx Its Visualization by Hysterosalpingography Albert Mathieu Calif and West Med, August, 1931, XXXV, 73-78

In discussing hydrosalpinx, the author depends a great deal on iodized oil and the X-ray findings for diagnosis. He discusses the various types of hydrosalpinx, namely, those with closure of the proximal end of the tube, with closure of the distal end, and with closure of both ends.

In discussing the etiology, he believes that most of these are due to gonorrhreal infections. However, some of them may be due to tuberculous or pyogenic streptococcus infection. From the history it is probable that the husband has infected his wife with an attenuated gonococcus, he having thought himself cured and married prematurely. The author

illustrates his article with many X-ray reproductions.

FRANCIS B SHELDON, M D

GENITO-URINARY TRACT (THERAPY)

Empyema of the Ureteral Stump Ralph L Dourmashkin Jour Urol, October, 1931, XXVI, 553-573

The writer employs the above term to designate a collection of thick pus within a dilated ureteral stump, following incomplete ureterectomy. The persistence of pyuria may follow non-tuberculous nephrectomies in which a diseased ureter has not been carefully followed down to the bladder and excised. Omission of proper care to the infected lower end of the ureter may lead to a condition described as empyema of the ureteral stump.

Since normal ureters rarely become infected following nephrectomy, it would seem that a requisite for an empyema of a ureter to develop would be a pre-existing diseased state of this organ.

The treatment consists of adequate drainage and lavage of the infected sac. If this is found impossible because of a stricture at the lower end of the ureter, the orifice may be enlarged by fulguration, or, finally, excision of the stump must be resorted to if the preceding therapy has been found inadequate.

The paper reviews several cases which are accompanied by roentgenograms illustrating the condition.

DAVIS H PARDOLL, M D

The Prostatic Problem John H Cunningham Canadian Med Assn Jour, October, 1931, XXV, 428-432

In considering the prostatic problem, the most important fact to be appreciated is that the prostate itself is but the primary factor producing urinary retention. The presence of this retention influences the activity of the kidneys, and, in consequence, reflects unfavorably upon the circulation. Thus, a medical aspect develops which becomes the most important part of the picture, and surgery is but the means of improving it. In view of our present knowledge of the requirements for pronounc-

cystoscopist and roentgenologist It will necessarily vary somewhat with each operator The usual cystoscopic table may be used, the side of the patient to be injected being next to the film The position must be exactly lateral An anteroposterior pyelogram is first made and studied, the patient's position being changed if a lateral view seems advisable Normally the shadow of the pelvis lies behind the second lumbar vertebra Congenital changes in the kidney and ureter, the orienting of densities suspected of being calculi, tumors in the kidney region, and many other conditions find an easier solution when a lateral pyelogram is taken in addition to the usual anteroposterior view

W W WATKINS, M D

Intravenous Pyelography Luigi Turano
Archivio di Radiologia, May-June, 1931, VII,
605-626

The author reviews 150 cases studied by him and brings out the advantages and limitations of the method in the study of various urologic conditions

E T LEDDY, M D

Diseases of the Biliary Tract Clinical and Surgical Aspects Claude F Dixon
Calf and West Med, July, 1931, XXXV,
1-5

The author comments on the literature and pathology of the diseases of the biliary tract He gives the various types and classifies these diseases, according to Judd and McIndoe, as follows (1) Acute cholecystitis, (2) metabolic cholecytic disease, with or without stones, and (3) clinical or functional cholecytic disease

Under metabolic cholecytic disease, with or without stones, is the so-called "strawberry gall bladder" In this the gall bladder may function normally and, unless the stone obstructs the cystic duct, there may be no symptoms

In the third group there may be typical symptoms yet no evidence of disease is found —either microscopically or grossly, yet relief is often had after removal of the gall bladder Cholecystography has been found a

great aid in the diagnosis of disease of the gall bladder The functional test should be used in corroboration with the clinical findings The most characteristic symptom of a diseased gall bladder is pain, and when this is present, removal of the organ gives permanent relief in the majority of cases

FRANCIS B SHELDON, M D

The Diagnostic Value of Intravenous Urography Bruno Bellucci Archivio di Radiologia, May-June, 1931, VII, 651-661

The author thinks that the greatest value of the method is in those cases in which the ascending method is contra-indicated or those in which its evidence needs supplementation or confirmation

E T LEDDY, M D

The Rôle of the Ureter in Lesions of the Upper Urinary Tract Solomon I Movitt Urol and Cutan Rev, October, 1931 XXXV, 647-649

The author is of the opinion that pathologic conditions of the ureter occur more commonly than the number of cases reported would lead one to believe From an anatomic standpoint the kidney pelvis is not an organ which sometimes fills up and at times empties itself It should be considered as a link between the kidney and the urine-conveying tract Hyer expressed the view that anatomically the renal pelvis is just the initial part of the urete which forms only an unnoticeable continuation of the pelvis

The points of interest in the physiology of the ureter, as mentioned by the author, are as follows (1) It is distensible, (2) it has natural points of constriction often accentuated under pathologic conditions, (3) it has mechanism at the ureteral orifice which prevents regurgitation from the bladder Wu slow and O'Connor, however, have demonstrated that in pathologic conditions reflux of urine can occur in man Hunner pointed out the significance of the ureter in the urinary system, and he also contended that focal infection should be considered as an etiologic agent in ureteritis and ureteral strictures The in-

vals of 15, 30, 60, and 90 minutes following completion of the injection

No alarming reactions were noted, though patients complained of a variety of minor symptoms. In only 18 cases were the results entirely satisfactory. In 13 cases, the upper urinary tract was not visualized, of these, final diagnoses were normal in 5, pyelonephritis (3), kidney tumor (2), perinephritic abscess (1), and renal tuberculosis (2).

W W WATKINS, M D

Ureteral Meatotomy A Clinical Evaluation
Neil S Moore Jour Urol, October, 1931, XXVI, 519-528

From a clinical and radiographic study of about seventy-five cases on which ureteral meatotomy had been performed, covering a period of seven years, the author feels justified in drawing the following conclusions:

(1) The operation, though comparatively minor, is technical and deserves just consideration.

(2) When properly applied, the high frequency meatome is effectual and safe. It is possible to continue work higher up the ureter at the same sitting. There should be no alarming complications.

(3) There has not been any stricture formation following the operation in any of the cases observed.

(4) In a clinical and radiographic study of a series of cases, and symptoms or signs of ureteral regurgitation, at any time following the operation, were absent.

(5) A number of cases have been found in which the ureteral opening was amply large to admit from seven to nine catheters after the passage of which there was temporary relief. The same cases have shown more permanent, if not definitely permanent relief following a good wide incision of the opening.

The writer has devised an instrument for performing the operation and illustrations of it are contained in the article.

DAVIS H PARDOLL, M D

Therapeutic Irradiation of the Ovaries
A C Siebert Calif and West Med, October, 1931, XXXV, 290

This paper takes up the therapeutic action

of roentgen rays and of radium when directed against the ovaries of women suffering from benign gynecologic affections, as well as from diseases remote from the sexual organs *per se*, but which are influenced by the ovaries. The opinions here presented are based on personal experience with some sixty patients.

The author then takes up the general considerations, such as the effect of ovarian activity on a healthy genital tract and the body generally, and the sensitivity to radiation of the epithelial constituents of the ovary, which is exceeded only by the lymphatic tissues.

In the use of radium for menostasis not over 800 milligram-hours should be used. For permanent amenorrhea the radium intrauterine dose must be from 1,200 to 1,800 milligram-hours, or from 35 to 40 per cent of a roentgen skin dose must be absorbed by the ovary. The best time for giving the dose is the first half of the intermenstrual period. In younger women the question of post-radiation pregnancy must be considered. This possibility is discussed by the author.

Under the heading of "Special Phases" he discusses the treatment of (1) *Benign uterine hemorrhage*, for which he prefers the roentgen ray. Good results, in his experience, measure up to a 100 per cent standard, provided the proper agent is used and an adequate dosage given. Contra-indications are uncertainty of diagnosis regarding the benign nature of the hemorrhage, the youth of the patient, extremely neurotic individuals and hypertension.

(2) *Painful menstruation*. Radiation menopause by means of the X-ray is justifiable if the patient has reached her fortieth year. The results in this case are very gratifying. Here the same contra-indications should be considered as given under "Benign hemorrhage."

(3) *Fibromyoma uteri*. Under this heading the question of whether the treatment should be given to the ovary or to the tumor alone is discussed. The author believes that the treatment should be directed to the ovaries. Here he gives as contra-indications the youth of the patient, acute and serious pressure symptoms, degeneration of myomas, pedunculated myomas, and infection, if acute. Sar-

ing a prostatic patient fit or unfit for surgical treatment, every patient with prostatic obstruction must be viewed in terms of renal and circulatory impairment, and should be given the advantages of most careful clinical and laboratory study to determine the best course to pursue

In order to give the general average of the prostatic patient, the author looked over his last 400 cases operated upon. The age varied from forty-four to eighty-nine years, and the greatest number of cases occurred between the ages of sixty and seventy. Associated defects were discovered as follows: Renal, over 90 per cent; circulatory, over 75 per cent; respiratory, over 20 per cent; nervous system over 25 per cent.

This great preponderance of renal and circulatory defects renders the determination of the condition of the kidneys and circulatory organs the most important feature of pre-operative study. Renal impairment will depend chiefly on the degree of the back pressure. This produces dilatation not only of the ureters but also of the kidney pelvis and calices, and a thinning of the renal cortex, whereby the secretory power of the kidneys is decreased. Infection superimposed upon these mechanical degenerative changes further diminishes efficiency of the kidneys. As a result of this diminished power of elimination of the kidneys, an increased burden is placed upon the heart. A definite cardio-renal complex and a varying degree of toxicity develop insidiously, with an abnormal nitrogen retention, and uremia is an inevitable consequence.

The deaths from prostatectomy, in olden days, occurred mostly from uremia, occasionally from sepsis, and, rarely, from hemorrhage. The mortality to-day depends upon the same factors, but much may be accomplished by pre-operative treatment in overcoming uremia and sepsis. As a consequence, the mortality has changed from about 30 per cent, twenty years ago, to about 5 per cent at the present time.

Bladder drainage is the most important feature of pre-operative treatment and is the means to the end of permitting the forcing of

fluids and an estimation of the recuperative powers of the individual.

The author goes into the details of operative treatment for the various types of prostatic obstruction, the nature and extent of the operation depending on the nature of the obstruction and the condition of the patient.

In cancer of the prostate the malignant obstruction should be removed through the perineum, if the patient's general condition permits of operation. If it is poor, and metastases are present, permanent suprapubic drainage is more appropriate, with or without subsequent treatment by X-ray or radium. Prior to operation the tumor should receive active radium treatment to lessen the vitality of the malignant cells, because during the operation the malignant mass is usually broken into and blood spaces are opened up which form avenues for the dissemination of the disease. At the time the gland is removed, radium should be left in the prostatic region for at least 500 millicurie-hours. After recovery from the operation, radium and deep X-ray therapy should be used.

L. J. CARTER, M.D.

Excretion Urography G. C. Burr and R. Dovitz Jour Michigan St Med Soc, August, 1931, XXX, 595-600

Attempt is made to evaluate this procedure on the basis of the first 50 cases examined by it in the Department of Urology of the Detroit Receiving Hospital. Excretion urography is still in the process of experimentation but it has evidently come to stay, as it has its value in special cases. Dynamics of the urinary tract can be studied only by this method. It will not supplant retrograde pyelography, which was necessary in 36 out of the 50 cases examined.

The technic was to inject 40 grams of iopax in 100 cc of double distilled water at body temperature. The patient was prepared by being given compound licorice powder at 5 p.m. the day before examination, cleansing enemas in the morning, no breakfast, no fluids 1/50 gr of eserine a half hour before injection, slow injection over a period of 15 minutes, with roentgenograms made at inter-

vals of 15, 30, 60, and 90 minutes following completion of the injection

No alarming reactions were noted, though patients complained of a variety of minor symptoms. In only 18 cases were the results entirely satisfactory. In 13 cases, the upper urinary tract was not visualized, of these, final diagnoses were normal in 5, pyelonephritis (3), kidney tumor (2), perinephritic abscess (1), and renal tuberculosis (2).

DAVIS H PARDOLL, M D

Therapeutic Irradiation of the Ovaries A C Siefert Calif and West. Med., October, 1931, XXXV, 290

This paper takes up the therapeutic action

of roentgen rays and of radium when directed against the ovaries of women suffering from benign gynecologic affections, as well as from diseases remote from the sexual organs *per se*, but which are influenced by the ovaries. The opinions here presented are based on personal experience with some sixty patients.

The author then takes up the general considerations, such as the effect of ovarian activity on a healthy genital tract and the body generally, and the sensitivity to radiation of the epithelial constituents of the ovary, which is exceeded only by the lymphatic tissues.

In the use of radium for menostasis not over 800 milligram-hours should be used. For permanent amenorrhea the radium intrauterine dose must be from 1,200 to 1,800 milligram-hours, or from 35 to 40 per cent of a roentgen skin dose must be absorbed by the ovary. The best time for giving the dose is the first half of the intermenstrual period. In younger women the question of post-radiation pregnancy must be considered. This possibility is discussed by the author.

Under the heading of "Special Phases" he discusses the treatment of (1) *Benign uterine hemorrhage*, for which he prefers the roentgen ray. Good results, in his experience, measure up to a 100 per cent standard, provided the proper agent is used and an adequate dosage given. Contra-indications are uncertainty of diagnosis regarding the benign nature of the hemorrhage, the youth of the patient, extremely neurotic individuals, and hypertension.

(2) *Painful menstruation*. Radiation menopause by means of the X-ray is justifiable if the patient has reached her fortieth year. The results in this case are very gratifying. Here the same contra-indications should be considered as given under "Benign hemorrhage."

(3) *Fibromyoma uteri*. Under this heading the question of whether the treatment should be given to the ovary or to the tumor alone is discussed. The author believes that the treatment should be directed to the ovaries. Here he gives as contra-indications the youth of the patient, acute and serious pressure symptoms, degeneration of myomas, pedunculated myomas and infection if acute. Sar-

comatous degeneration and carcinoma of the body of the uterus, in the author's opinion, are not contra-indications, for here pre-operative irradiation would be a distinct benefit. These two conditions, associated with uterine fibromyomas, are, however, rather rare complications.

(4) *Chronic infections of the uterus and adnexa* may be favorably influenced by roentgen-ray therapy. The guiding principle here is the observation that the periodic congestion of the pelvic organs, incident to menstruation, adversely affects the infectious process. Therefore, temporary or permanent menostasis may be accomplished.

(5) *Diseases outside the genital tract*. Carcinoma of the breast therapy in young women is oftentimes helped by stopping the menstrual function. Also, in toxic goiter, the cessation of the menstrual function often causes the metabolic rate to drop sharply. Advanced pulmonary tuberculosis, with slight hemorrhage, is favorably affected by menostasis.

FRANCIS B SHELDON, M.D.

Large Coralliform Kidney Stones and Their Treatment James Thomas Nix Urol and Cutan Rev, October, 1931, XXXV, 631-634

The author discusses two cases, presenting large coralliform kidney stones, and the methods of treatment employed.

The first case record was that of a white female, 55 years of age, who complained of dull pain in the left lumbar and lower dorsal regions. A stone had been removed from the left kidney nineteen years previously. Three years before admission, following an attack of severe pain of 48 hours' duration in the left lumbar region, the patient passed a stone in the urine and felt very much relieved. X-ray examination at this time revealed a large stone in the left kidney. Two weeks before seeking admission the patient again experienced a similar attack of pain. Operation at this time revealed a large coralliform stone, with destruction of the kidney structure. Nephrectomy was accordingly performed and the patient made an uneventful recovery.

The second case was that of a white male,

43 years of age, who, while at work, "felt something drop inside of him." Following this he suffered from rather sharp pains in the lower abdomen, associated with frequent and painful urination. Roentgen examination revealed a bladder calculus and large stones in the kidneys. The phenolsulphonephthalein test at this time was 55 per cent. Urinalysis revealed red blood cells and pus. The bladder stone was removed by suprapubic cystotomy, uneventful recovery resulting. After discharge from the hospital the patient disappeared for three years. He returned because of pains over the right kidney region. X-ray examination showed an increase in size of the calculi previously observed. The phenolsulphonephthalein test at this time was 45 per cent, and gradually decreased to 15 per cent. While this patient's condition has remained practically stationary, the author considers that the real chance for a cure was lost when he failed to return after the cystotomy, as he had been instructed.

The author offers suggestions for consideration in the treatment of large coralliform calculi. Unilateral stones, in cases in which the opposite kidney is good, should be removed by pyelotomy or pyelonephrotomy. Nephrectomy should be reserved for those cases in which the kidney is destroyed. Slight impairment of the opposite kidney is not a contra-indication, but often aids in the restoration of function on the side upon which operation has been done.

Cases of bilateral stag-horn calculi are divided into two groups. The first group includes those patients in poor physical condition because of pathology elsewhere. In this type of case surgical measures should be postponed until the patient's condition improves. The second group includes those cases in which there is some disproportion in the involvement and infection present on the two sides. Surgical intervention is permissible in those cases in which the calculus may be removed without causing much kidney damage. A sufficient interval should always be allowed between operative procedures on the separate kidneys to permit satisfactory repair and restoration of function of the kidney operated upon. The patient should in any case be kept

under a constant observation which should include urinalysis, functional tests, and roentgenograms

J N ANE, M D

GYNECOLOGY AND OBSTETRICS

Roentgenographic Diagnosis of Diseases of the Breast Paul S Seabold *Surg, Gynec and Obst.*, October, 1931, LIII, 461-468

The author describes the normal breast as having continued changes caused by age, adiposity, puberty, menstrual cycle, menopause, and pre-existing pathology

Breasts before puberty are difficult to show radiographically. Breasts before the climacterium vary in architecture by the stage of the menstrual cycle. There is a triangular area in a breast, with the apex towards the nipple. This is shadowed by well-defined lines which are cast by the lactiferous ducts and their fibrous tissue. The first few days after menstruation begins these lines are increased in density, are clear cut, and radiate from the main ducts just behind the nipple. This is called the striated breast triangle. These striations become less distinct as the next period approaches and then are wave-like. Striations at right-angles are developed, which reach a maximum opacity ten days prior to the beginning of menstruation. The breast reaches its greatest compactness at this time. Normal lymph nodes do not cast a shadow.

Little change is noted in a breast before six months of pregnancy. After this time the wave-like appearance is more pronounced and heavier.

After the menopause the triangular striations are crowded together, producing a heavier, more dense triangle. Small oval masses of density caused by small cysts may be seen.

Malignancy of the breast is shown by the disruption of the normal triangle, and in place of striations there is a concentric, whorling appearance, with greatest opacity at the central portion of the mass, the edges of which are quite irregular. In many tumors there is a broad-like radiation from the tumor mass to the nipple. Metastasis is demonstrated as a

faint opacity cast by pectoral or axillary lymph nodes. However, nodes of inflammatory origin may have a like appearance although perhaps a little less dense. Differentiation of abnormal involution from malignancy is difficult, but involution is shown as small oval areas of varying density with well-defined borders.

Benign tumors are localized, do not spread, have well-defined borders, and the linear triangular striations are crowded to one side to make room for the growth. A cyst is less dense than a solid tumor.

There is no bibliography given.

DONALD S CHILDS, M D

Studies of the Time Factor Hermann Wintz *Strahlentherapie*, Oct 24, 1931, XLII, 591-598

The effect of the time factor on the reactions following irradiation was studied in cases which received a sterilizing dose of roentgen rays. If 34 per cent HED effective in the ovaries was applied in one single sitting on the fifth day after the beginning of the menstruation, 95 per cent of these patients did not menstruate any more, and 5 per cent had one more menstruation. After three years all cases still had amenorrhea. The same result was obtained if the same dose was given in one sitting on the eighth day after the beginning of the menstruation.

In another group, 17 per cent HED was given on the fourth and 17 per cent on the eighth day after the beginning of the menstruation. In 21 per cent, one menstruation occurred, in 32 per cent, two menstruations, in 45 per cent, three menstruations, and in 2 per cent, four menstruations after the treatment. Three years later, 78 per cent had still amenorrhea, while in 2 per cent menstruation recurred after the first year, in 15 per cent after the second year, and in 5 per cent after the third year.

Another group received 20 per cent on the fourth and 20 per cent on the eighth day after the beginning of the menstruation. One menstruation occurred in 72 per cent, two menstruations in 24 per cent, and three menstruations in 4 per cent of the cases after the

treatment Amenorrhea was present in all cases three years later

Another group received 25 per cent on the fourth day and 25 per cent H E D on the eighth day after the beginning of the menstruation After the treatment, 86 per cent had no menstruation, 12 per cent had one, and 2 per cent of the patients, two Amenorrhea was still present in all patients three years later

The next group received 28 per cent of the H E D on the fifth day after the beginning of the menstruation One menstruation occurred in 12 per cent, two in 22 per cent, three in 57 per cent, and four in 9 per cent of the patients After three years all patients were menstruating again, the period of amenorrhea having varied from twenty-three to thirty-one months

The last group received 14 per cent H E D on the fourth day and 14 per cent on the eighth day after the beginning of the menstruation In sixteen women the menstruation was not interrupted In one patient the menstruation stopped for three months, beginning six months after the treatment, and in another patient it stopped for four months, beginning five months after the exposure

The figures of this statistical survey are self-explanatory In comparing the susceptibility of the graafian follicles and of the primordial follicles it appears that the cells with more active mitosis recover much easier, while the cells at rest cumulate the applied dose almost completely

ERNST A POHLE, M D , Ph D

Is the Oviduct Open? Lawrence D Smith Jour Iowa St. Med Soc, February, 1931, XXI, 77-80

The answer to a patient's query as to why she cannot become pregnant is not always easy A complete history of wife and husband is necessary, then a thorough physical examination of both If both are found to be normal, the patency of the oviducts is tested by injecting them with iodized oil under fluoroscopic guidance If the tubes are occluded, re-radiate in twenty-four hours The author discusses the therapeutic value of this procedure Contra-indications are given as

carelessness and incompetency, recent uterine bleeding, active infection, recent uterine intervention, uterine pregnancy, malignancies or polyps of the uterus, fever, latent streptococcic salpingitis

W W WATKINS, M D

Traumatic Separation of the Symphysis Pubis Ward L Ekas Am. Jour Obst. and Gynec., May, 1931, XXI, 681-689

According to reported cases, separation of the symphysis pubis occurs infrequently in pregnant women It is estimated as occurring in about one out of 25,000 cases Wishner and Mayer believe it is not as rare as supposed but is often overlooked Separation of the symphysis is often associated with injury to the sacro-iliac articulation The amount of separation of the symphysis which can occur without having an associated sacro-iliac injury has been variously estimated by different authors from 3 millimeters to 7 centimeters

Traumatic separation of the symphysis pubis may be caused by falls, severe strains, forcible separation of the thighs, and internal pressure as in pregnancy Predisposing causes are diseases of the pelvic joints, disproportion, increased mobility during pregnancy, or repeated pregnancies Kehrer describes the formation of cavities or softening in the pubic cartilage or capsule as a predisposing cause Caries, rachitis, osteomalacia, chronic arthritis, trauma during pregnancy, and congenital weakness may predispose toward rupture Sixty-seven per cent of DeLee's cases occurred in forceps deliveries

Prognosis is, as a rule, good Complications, as ruptured bladder, fever and sepsis, embolus, are often serious There is rarely a return when the capsule is torn and subsequent labors are usually easy

JACOB H VASTINE, M D

Eight Years' Experience with Roentgen Diagnosis in Gynecology Pneumoperitoneum and Lipiodol in Pelvic Diagnosis Irving F Stein Am Jour Obst and Gynec., May, 1931, XXI, 671-679

Pneumoperitoneum and lipiodol in pelvic

diagnosis are methods of precision and accuracy. They are safe if ordinary care and skill are employed and if the indications and contra-indications are carefully observed. The contra-indications to lipiodol instillation are bleeding from the uterus, pregnancy, infected interi, and virginity. No accident or complication was encountered by the author in 530 cases of pneumoperitoneum, in 200 of which lipiodol was also employed.

In cases of sterility, the Rubin test should first be employed to determine the patency of the tubes. Introduction of an opaque oil into the uterus, in addition to the Rubin test, is often necessary and demonstrates the point of obstruction. The size and shape of the uterine cavity are of importance. To attempt to diagnose tumors, cysts, and tubal pregnancy by lipiodol instillation is apt to lead to error. For intra-uterine pregnancy it is meddlesome, dangerous, and should be avoided.

Pneumoperitoneum in pelvic diagnosis—A liter of CO₂ is introduced into the peritoneal cavity either by the transuterine or transabdominal route, according to the method described by Peterson in 1921. The uterus, ovaries, fallopian tubes, and bladder are regularly shown and the round ligaments are sometimes seen. The presence or absence of pelvic viscera, when in question, hypoplasia, etc., are demonstrable. Adhesions of the viscera can usually be demonstrated. Intra- and extra-uterine pregnancy (from five to six weeks' duration), lutein, and other cysts of the ovary may be graphically differentiated. Fibroids can usually be easily differentiated.

Combined lipiodol instillation and pneumoperitoneum have been used by the author in over 200 cases and found to be advantageous in establishing the correct diagnosis.

JACOB H VASTINE, M D

HEART AND VASCULAR SYSTEM (DIAGNOSIS)

Contributions to the Study of Congenital Malformations of the Heart Antonino

Perez Ara Rev Medicina y Cirugia, Havana, Sept 30, 1931, XXXVI, 657-682

The author gives in this paper a fair outline of congenital malformations of the heart. He presents the case of a goat with an extrathoracic heart, showing pictures and radiographs of the same. In this case, the auricles were inside the thorax, while the myocardium was outside.

N G GONZALEZ, M D

The Importance of Anomalies of the Superior Vena Cava in Man J Beattie Canadian Med Assn Jour, September, 1931, XXV, 281-284

The author refers to the work of Kohler in calling attention to the importance of a careful study of the aortic arch and associated vessels in roentgenograms of the thorax. The superior vena cava is visible in almost every case after the thirty-fifth year, forming a part of the "aortic" or "vascular" shadow in frontal and oblique films. In oblique views the so-called "aortic shadow" has its posterior edge formed by the superior vena cava, or the vena cava projects a little way behind it. It follows, therefore, that an estimate of the diameter of the aorta must take into account the position and size of the superior vena cava. Hence, anomalies of the large venous trunks in the upper thorax take on some practical importance in the radiologic diagnosis of thoracic conditions.

The main venous trunks of the head and arm in the early embryo consist, as in the adult, of an internal jugular vein and a subclavian vein which unite to form a large venous trunk on each side of the body. These veins (the "anterior cardinal" veins of the embryologist) pass vertically downward into the thorax and unite with two corresponding posterior cardinal veins to form two (a right and a left) large venous trunks which enter the primitive heart. Cross-anastomoses between the two anterior cardinal veins are developed but only one of these, which lies at the root of the neck, persists in the adult. Changes take place in the lower part of the left anterior cardinal vein which result in the switching of all the blood from the left side

of the head, neck, and left arm and from the left anterior cardinal vein into the right anterior cardinal by way of the cross-anastomosis between the two veins. Parts of the left anterior cardinal vein persist, but are not normally in continuity with the upper part of the original vessel. The cross-anastomosis between the two primitive cardinal veins becomes the left innominate vein.

From a practical standpoint, anomalies of the superior vena cava can be divided into three classes: (1) Persistence of both primitive anterior cardinal veins and the normal cross-anastomosis between them; (2) persistence of both primitive anterior cardinal veins, but with no cross-anastomosis between them; (3) persistence of the left anterior cardinal vein, with obliteration of the right. Persistence of the right anterior cardinal vein with obliteration of the left is the normal arrangement.

The author has been able to find 175 cases of abnormalities of the superior vena cava, including the three which he himself reports. He concludes that these abnormalities are not incompatible with life, and that Types 1 and 2, as indicated above, are more numerous than Type 3.

The three cases reported by the author illustrate the three types as classified above. They were all obtained postmortem from bodies of adults ranging from 50 to 70 years. They illustrate three stages in the transition from the normal to the completely abnormal condition of a left superior vena cava. The first specimen showed a left superior vena cava alongside a fully developed right vena cava. The second resembled the first, but there was no cross-anastomosis, whereas there was a small one in the first specimen. The third specimen represented the complete abnormality in that the right vena cava was entirely absent, while a left vena cava was fully developed. A cross-anastomosis drained the blood from the right side of the face and neck into the left vena cava.

L J CARTER, M D

Traumatic Aneurysm of the Subclavian Artery as a Late Complication of Fractured

Clavicle E H Cayford and F J Tees
Canadian Med Assn Jour, October, 1931,
XXV, 450-452

This is a case report of a young man, aged 22, who, while playing football, in 1926, broke his clavicle in a forward lunge across the turf. A surgeon set it with apparently good result. His father recalls that at the time there was a great deal of swelling. No X-ray films were taken.

In January, 1931, he complained of pain and tingling in the left arm and hand, the latter also being cold. He had noticed that the pulse of the left wrist had disappeared. Examination showed a large callus at the site of the old fracture, about the middle of the left clavicle, and a palpable mass behind it. The mass was not definitely expansile, though pulsation was easily felt. Auscultation above the clavicle revealed no bruit. X-ray examination showed a rounded tumor, $3\frac{1}{2}$ cm in diameter situated behind the left clavicle and in contact with it. At operation the clavicle was dissected off the mass, and a clearly defined aneurysm of the subclavian artery was found. It was the size of a walnut and wedged in between the clavicle and the first rib. It was calcified laterally and fixed behind and in front to the first rib and the clavicle. The main portion of the mass was removed, a modified Matas endo-aneurysmorrhaphy being done. The repair was supported with the sheath of the subclavian muscle.

About four weeks later a mass appeared suddenly at the site of operation, accompanied by excruciating pain about the neck and arm. At operation a large laminated clot was found lying between the tissue layers. On manipulation the clot gave way and the gush of arterial blood was stopped by corking the artery with the finger. Ligatures *en masse* were passed until all bleeding ceased, the vein as well as the artery being occluded in the process. There was some edema of the extremity during convalescence and considerable pain in the index finger and thumb, but capillary circulation was maintained and the arm and hand remained warm. When last seen, about four months later, there was no evidence of sensory or motor disturbance and the patient enjoyed the full use of the arm.

The authors conclude that it would have been better to have adopted a less conservative attitude at the first operation, and at that time to have tied off the artery and accompanying vein

L J CARTER, M D

A Case of Enormous Antemortem Dilatation of the Heart Antonino Nicotra Archivio di Radiologia, May-June, 1931, VII, 473-479

A boy, 22 years of age, had an X-ray examination made of his thorax. The radiograph (illustrated) showed a median shadow occupying three-fourths of the right hemithorax. Without autopsy control, the author thinks it a case of enormous dilatation of the right auricle and ventricle, since all other possibilities were eliminated in making the diagnosis

E T LEDDY, M D

A Case of Multiple Aneurysms of the Aorta and Great Vessels H F Mowat. Canadian Med Assn Jour, October, 1931, XXV, 453, 454

Multiple aneurysms are usually more frequent in the larger arterial trunks, especially the thoracic aorta. Klotz collected 695 cases of thoracic aneurysm, and found that 70, or 9.8 per cent, were multiple in type. The series included saccular, dissecting, and fusiform varieties. Colt made a comprehensive survey of aneurysms in the British Isles, and found 575 dependable records of thoracic aneurysm. Multiple saccular dilatations were found in 59, or 9.1 per cent. Boinet reported 31 cases of multiplicity in 340 cases of thoracic aneurysms, or 11 per cent.

The author reviews 26 cases of aneurysm of the thoracic aorta found in 1,862 autopsies performed in the Department of Pathology of the University of Toronto since 1925. Of these, two cases were multiple. Both were due to syphilitic invasion of the arterial wall. Campbell Howard points out that this is always the cause of the multiple saccular type of thoracic aneurysms. This point is borne out by Graves, who reports 45 thoracic aneurysms

occurring in 1,595 postmortem examinations. Of these, six were multiple, and all six were due to syphilis.

The case reported by the author was that of a white male 55 years old, by occupation an iron worker. The family history was negative. No history of abortions or premature deliveries by his wife was given. Syphilis was denied. There was no history of alcoholism or the use of tobacco. His complaints were of hoarseness and a non-productive cough of five months' duration. There had been a loss of fifteen pounds in weight. Slight dyspnea and mild attacks of dizziness were complained of on exertion. There was complete paralysis of the right vocal cord.

X-ray examination of the chest revealed an aneurysm of the ascending aorta and the innominate artery. The blood Wassermann test was strongly positive. Following intensive anti-syphilitic treatment the patient returned to work after three months. Subsequently, he died suddenly on the street.

The postmortem findings were those of multiple aneurysms of the thoracic aorta, beginning at the aortic cusps and the sinuses of Valsalva, the innominate artery, the subclavian artery on the left side, and the transverse aorta. The right recurrent laryngeal nerve was adherent to the aneurysm of the arch, and was atrophied.

L J CARTER, M D

Heart Conditions Simulating Acute Abdominal Symptoms Gerald R Burns Canadian Med Assn Jour, October, 1931, XXV, 424-428

This is a presentation and analysis of a number of cases, with the idea of showing that, without the X-ray or electrocardiograph, a differential diagnosis can be made and the important decision as to medical or surgical treatment indicated. The author states that within the last fifteen months he has seen four cases of coronary artery thrombosis which were sent into the hospital with the diagnosis of acute abdominal emergency.

Three illustrative case histories are cited. The first, a farmer, aged 46, was admitted,

complaining of severe abdominal pain, centered in the epigastrum. He was in a condition of shock. The diagnosis was ruptured gastric ulcer. He had a history of acute rheumatic fever seven years before. During the past two years he had experienced increasing shortness of breath, and had had several attacks of moderately severe pain in the stomach, diagnosed as acute indigestion. The admission diagnosis was not confirmed, but a diagnosis of coronary artery thrombosis was made. This was confirmed later by the electrocardiograph.

The second, a farmer, aged 45, was admitted complaining of severe pain below the sternum. The diagnosis was acute abdomen. After examination, a diagnosis was made of coronary artery thrombosis, and the patient was saved an unnecessary operation called for by the admission diagnosis.

The third, a farmer, aged 46, was admitted, with a history of two years' duration of attacks of abdominal pain, centering in the epigastrum and relieved by vomiting. A diagnosis of angina pectoris was made.

In all of these cases, in spite of the apparent reference to the abdomen, there were definite heart findings, which should have indicated the diagnosis. In all, the heart was enlarged to the left, there was some cyanosis, usually a precordial rub or friction sound, no definite localized area of acute tenderness in the abdomen, and the pain was made worse by exertion.

Thrombosis of the coronary artery is by far the worst offender in the class of cardiac conditions which may offer some difficulty in differentiation from acute abdominal conditions. There is an acute attack of angina not relieved by amyl nitrite but only by repeated large doses of morphine. When the pain, instead of radiating down the arm, radiates toward the abdomen, as in the cases cited, the diagnosis offers some difficulty.

In the examination of the patient, one of the most important points is that the history of the illness should be unbiased and accurate. Special attention should be given to the family history, as regards death from high blood pressure, apoplexy, angina pectoris, and so-

called acute indigestion, or any sickness on the patient's part that might lead up to these conditions.

The characteristic things that point to coronary thrombosis are (1) The tinge of cyanosis about the tips of the nose and fingers, the lobes of the ear, and lips, (2) the stillness of the patient, as contrasted with the restlessness of the abdominal patient, (3) the drop of the blood pressure from a previously high level, (4) the enlarged heart, which is rapid, (5) the adventitious heart sounds which are usually present.

The fever, upper abdominal tenderness, leukocytosis, and pain in the epigastrum, are more or less features common to coronary thrombosis and acute abdominal conditions, and offer no special aid in the differential diagnosis. Angina pectoris is differentiated by the fact that the pain produced by it is relieved by amyl nitrite, while the pain of coronary artery thrombosis is relieved only by large doses of morphine.

The electrocardiograph gives a characteristic tracing.

L J CARTER MD

CHEMICAL ABSTRACTS

The Magnetic Spectrum of α -rays from the Active Deposit of Actinon. Mme P Curie and S Rosenblum. Compt rend., 1931, CXIII, 33-35.

The source of Act has previously been described. The oxides obtained from the oxalates were dissolved in HNO_3 , and La was precipitated with NH_4 . Part of the Act X was then precipitated with $(NH_4)_2CO_3$, and later converted to the fluoride. The remainder was carried down with $Fe(OH)_3$. Both products were used to obtain an active deposit by placing them in a brass tray having an insulated cover on which was attached a bit of Au (2×0.01 cm.). An electromotive force of 1,000 V was set up and the active deposit collected on the Au cathode, with about 30 per cent yield in eight days. By means of a large electromagnet the following ratios were measured: $V_{\alpha}/V_{\alpha} = 0.973$ and $V_{\alpha'}/V_{\alpha} =$

where V_α is the velocity of the more intense of the two strong rays, α and α_1 , due to Act C, and V_{α_2} is the velocity of the weak ray due to Act C' The difference $\alpha - \alpha_1$ corresponds to 352 KV electrons, a group of γ -rays of this energy is attributed to Act C"

Temperature Effect in Diffuse Scattering of X-rays from Rock Salt W D Claus Phys Rev, 1930, XXXV, 1427

Experiments conducted to test the effect of temperature on the scattering of X-rays indicate in the range from 295° to 135°, a much smaller decrease than that expected from the Debye equation

CHEMICAL ABSTRACTS

Diffuse Scattering of X-rays from Sylvine at Low Temperature G E M Jauncey and G G Harvey Phys Rev, Dec 1, 1931, XXXVIII, 1925-1931.

By use of a modification of the photographic method described by Claus, the authors have compared the intensities of X-rays of wave length 0.43 Å, diffusely scattered from sylvine at angles in the range 25° to 90° at a temperature of 90° K, with the intensities at these same angles at a temperature of 300° K The authors have shown that the intensity of the diffusely scattered rays should be given by $S = S' - F^2/Z$, where S' is independent of the temperature and F is the atomic structure factor containing the effect of thermal agitation With James and Brindley's F values at 90° K and 300° K, theoretical values of S for 90° K have been calculated The experimental S values at 90° K are lower than the theoret-

tical S values This result is in accord with that found by Claus for rock salt Plotting $\log (S' - S_1)/(S' - S_2)$, where the subscripts refer to the two temperatures, against $(\sin^2 \phi/2)/\lambda^2$, a straight line is obtained whose slope agrees with that required by the Waller and not the Debye formula for the temperature effect It is impossible by means of this experiment to show whether or not there is zero point energy In order to do this, an assumption concerning the electron distribution in the atom must be made

THE AUTHOR

Higher Order Effects in the Diffraction of X-rays by Liquids W C Pierce Phys Rev, Oct 15, 1931, XXXVIII, 1413-1419

The X-ray diffractions of liquid carbon tetrachloride, chloroform, benzene, solutions of carbon tetrachloride in benzene, o-dichlorbenzene and m-dichlorbenzene have been determined for $MoK\alpha$ rays by the ionization spectrometer All give a main peak characteristic of liquids and, in addition, the halogen compounds give other maxima in the intensity-angle curve at large angles This effect is the same for carbon tetrachloride, pure or in solution, and is consequently thought to be due to internal interference caused by scattering from the chlorine atoms Debye's relation for the scattering of single atoms cannot be applied because the positions of the peaks obtained from solutions are masked by the molecular scattering of the solvent

THE AUTHOR

The Regular Reflection of X-rays from Quartz Crystals Oscillating Piezoelectrically Gerald W Fox and James M Cork Phys Rev, Oct. 15, 1931, XXXVIII, 1420-1423

Laue patterns from quartz crystals oscillating piezoelectrically have been observed to be more intense than similar patterns from non-oscillating crystals In this investigation, regular Bragg reflections from the face of crystals oscillating and non-oscillating have been observed in order to notice any variation in intensity or line width No effect of this kind

has been observed These results are interpreted as negating the existence of Zwicky blocks, rocking slightly by the piezoelectric oscillations, as proposed by Langer An explanation of the observed effect with Laue spots based upon the extinction effect in perfect crystals is proposed

THE AUTHOR

Precision Measurements of Air Ionization by Roentgen Rays of Definite Hardness and Homogeneity in Barrel Chambers of Smallest and Largest Size Hans Kustner Strahlentherapie, Oct 3, 1931, XLII, 337-343

The author determined the error in absolute measurements of the r due to an unsuitable diameter of the ionization chamber Curves are presented giving quantitative data on the influence on the end-result of chamber volume, homogeneity of radiation, and scattering within the chamber The author emphasizes the many precautions necessary in carrying out precision measurements and suggests that his data, rather than inadequate determinations be used for corrections

Lateral Space Distribution of X-ray Photo-electrons Paul Kirkpatrick Phys Rev, Dec 1, 1931, XXXVIII, 1938-1942

The lateral distribution in space of the directions of emission of photo-electrons ejected from argon atoms by partially polarized X-rays having the mean wave length 0.53 Å was determined by examination of photographs of 2,008 condensation tracks produced in a C T R Wilson expansion apparatus Discarding by a definite analytical procedure the isotropically distributed emissions, which are ascribed to unpolarized radiation, the distribution of the remaining 752 tracks is found to be in excellent agreement with the indications of quantum mechanics that (for K electrons) the probability of emission is proportional to the square of the cosine of the angle between the electric vector of the absorbed radiation and the projection of the direction of emission upon a plane normal to the direction of incidence

THE AUTHOR

The Reasons for the Broadening of X-ray Diffraction Lines with Powder and Rotating-crystal Photograms U Dehlinger Ztschr Metallkunde, 1931, XXIII, 147-149

The broadening of diffracted X-ray lines may be ascribed to three fundamental crystallographic conditions gradual variations within the lattice, abnormally small grains, abrupt variations within lattice Gradual variations may be of two types variations in lattice parameter originating in concentration differences in solid solutions, and those originating in elastic distortion The variations in lattice constant must be approximately constant within a range of at least 0.5μ . A concentration variation of 3 per cent Zn in a Cu-Zn alloy will cause a broadening equal to the distance between the lines of the $K\alpha$ doublet from Cu Elastic distortion, caused by strains, must likewise be approximately constant within a range of 0.5μ . Failure to fill this condition results only in a displacement and of a broadening of line A grain size less of pressure and temperature of the I_2 vapor gave the effective cross-section in collisions of the excited Na atoms with I_2 molecules or atoms In the first case a corresponding decrease in effective cross-section was found for increase in velocity of the Na atoms For collisions with I_2 atoms the effective cross-section is about ten times smaller than the maximum value for collisions with molecules and shows no decided dependence on velocity

CHEMICAL ABSTRACTS

Absorption of Soft X-rays in Gases R G Spencer Phys Rev, Dec 1, 1931, XXXVIII, 1932-1936

A crystal spectrograph for measuring absorption coefficients of soft X-rays in gases has been constructed, and with it absorption coefficients of air, argon, and oxygen have been measured for spectral lines of wave lengths 1537, 2284, 4145, and 6973 Ångströms Absorption coefficients in the regions immediately adjacent to the K absorption limit of argon have been measured with general radiation No departure from the ordinary absorption law greater than experimental error

was found in these regions The magnitude of the K absorption discontinuity of argon was measured by a method which is not dependent upon the extrapolation of curves to the absorption limit, and also by a method which is independent of the absolute magnitude of the absorption coefficients on either side of the absorption limit

THE AUTHOR.

The Production of Intense Monochromatic X-rays with Technical Tubes without Spectral Apparatus Hans Kustner Ztschr Physik, 1931, LXX, 324-347

By means of a differential method, using selective filtering, very intense and highly monochromatized radiation was obtained The $K\alpha, \alpha'$ doublet was obtained practically pure

CHEMICAL ABSTRACTS

The Effect of General Radiation in the Diffraction of X-rays by Liquids W C Pierce Phys Rev, Oct 15, 1931, XXXVIII, 1409-1412

Previous work has shown that the amount of general radiation transmitted by a single filter may cause peaks in the diffraction pattern of liquids Balanced strontium and zirconium filters are used to study the magnitude of this effect in X-rays from a molybdenum tube operating at 35 KV Zirconium alone does not give sufficient filtration under these conditions, but by use of the two filters the effects of the general and characteristic radiation may be completely separated

THE AUTHOR.

The Scattering of X-rays from Paraffin, Aluminum, Copper, and Lead Allen W Coven Phys Rev, Oct 15, 1931, XXXVIII, 1424-1431

The radiation from a tungsten-target X-ray tube operated at 80 KV was filtered through 0.244 cm of aluminum, and the intensities of the scattered radiations from paraffin, aluminum, copper, and lead were observed by the ionization method The scattered intensities at angles in the range of 30° to 120° with the forward direction of the primary beam were

compared with the scattered intensities at 90 degrees. Values of the intensity at 90° for paraffin were compared with the intensity at 90° for the other materials. The scattering from paraffin and aluminum was at an effective wave length of 0.32 Å, from copper 0.26 Å, and from lead 0.27 Å. The Dirac value of the scattering from paraffin at 90° was used as the basis for calculating the absolute values of the scattering per gram and the scattering per electron.

THE AUTHOR.

A Classical Effect of the Scattering of Radiation Otto Halpern Ztschr Physik, 1931, LXVII, 523-530

It is pointed out that the light scattered by an isolated oscillator consists not only of the coherent radiation due to the forced vibrations, but also of those frequencies which correspond to the proper frequencies of the oscillator. This is illustrated by calculating the scattered radiation when a wave of sharply cut head and tail acts on the oscillator. These considerations are also interpreted quantum-mechanically with the use of relations of Weisskopf and Wigner for the shape of a spectral line. To observe this effect, experimentally, light near the proper frequency ought to be used, or X-rays of suitable wave length.

CHEMICAL ABSTRACTS

Origin of the Gamma Rays Lord Rutherford and C D Ellis Proc Roy Soc London, C, 1931, CXXXII, 667-688

A lengthy discussion is given on radiation

and disintegration transitions from excited nuclear states, and radiationless transitions and general complexity of β-ray spectrum. All existing data on energies of γ-rays are listed and classified with an attempt to deduce a "level" system. It is found that there is, seemingly, a possible classification, inspection shows that the difference in energies between a number of the lines is approximately 0.4×10^{-5} electron-v or a multiple of this number. It is attempted to see whether the energies of the γ-rays can be formulated by an expression of the type $E = pE_1 - qE_2$, where p and q are integers and E_2 is a constant which is small compared to E_1 . Curves showing the success of the analysis are given.

CHEMICAL ABSTRACTS

A Small Contribution to the Chapter of Physiologic Effects of Atmospheric Electricity C Dorno Strahlentherapie, Sept. 12, 1931, XLII, 87-95

The author has written this brief article in honor of the fiftieth birthday of Professor Dessauer (Frankfort on Main). He states that the atmospheric electricity undoubtedly causes physiologic effects. The case of a major is related who, because of war injuries, suffered from tinnitus. He kept a diary for a period of several years showing the type of noise experienced during the hours of the day. Comparison of the curves plotted from these data with the changes in the atmospheric electricity showed very definite relations. Dessauer's experiments with air charged unipolar will in all probability throw further light on this interesting phenomenon.

IMPORTANT ANATOMICAL DATA OF THE DIGESTIVE TRACT¹

By THE COLE COLLABORATORS

KNOWLEDGE of certain anatomical facts concerning the various parts of the digestive tract is very essential, both to an understanding of the findings observed, and for an intelligent and accurate application of the roentgenologic method of examination in eliciting the information that is desired. In the following section it is not our intention to review completely the anatomy of the digestive tract, but, rather, to point out the essential anatomical facts, some of which are common knowledge, but others of which are seldom, if ever, referred to in the standard or even in the special textbooks of anatomy.

Anatomy of the Esophagus—The esophagus is a musculo-muco-membranous canal which extends from the pharynx to the stomach. The anatomical relations of the esophagus as observed roentgenologically are illustrated in Figure 20. It commences superiorly at the upper, posterior border of the cricoid cartilage, and terminates inferiorly about from 3 to 5 cm below the diaphragm at the cardiac orifice of the stomach. The esophagus descends along the front of the vertebral column, and, except in the cervical region and abdomen, lies in the posterior mediastinum. In the cervical region the esophagus lies between the vertebral column and the larynx and trachea. In the thorax it lies in close relation anteriorly from above downward with the trachea, the left main bronchus, and the pericardium, i.e., the posterior surface of the heart. The anterior part of the arch of the aorta is in front of the esophagus and is separated from it by the trachea, but in the upper mediastinum the terminal (posterior) part of the arch of the aorta is in contact with the left side of the esophagus.

The general direction of the esophagus is vertical, but it presents several lateral curves and also slight anteroposterior curves corresponding to the curvature of the cervical and thoracic portions of the vertebral column. The lateral curves are more marked when the individual is in the recumbent posture, due to the release of the tension on the esophagus which is present when one is erect. As regards the lateral curves the esophagus at its commencement

¹Presented at the Third International Congress of Radiology, Paris, July, 1931, by Lewis Gregory Cole M.D.

is in the median line, but inclines to the left in the lower cervical region so that it lies partially behind the left lobe of the thyroid. In the upper thorax the esophagus gradually passes to the mid-line again, and in the lower thorax, about 5 cm above the diaphragm, it inclines to the left and forward away from the vertebral column. Below the diaphragm it still inclines forward and to the left to join the stomach.

The caliber of the lumen of the esophagus varies with the presence or absence of swallowed substances, and varies considerably with the size of the bolus passing through it. The caliber is also anatomically somewhat irregular. Many points of narrowing have been described, but those of chief importance are at the introitus, at the level of the aortic arch, at the crossing of the left bronchus, at the level of passage through the diaphragm, and at its termination—the cardiac orifice of the stomach.

The close relation of the esophagus to the posterior part of the arch of the aorta in the upper mediastinum, and the posterior surface of the heart below the level of the bifurcation of the trachea, is of considerable importance. Changes in size and shape of these parts of the heart and aorta are directly reflected in displacement of and pressure on the esophagus. Therefore, roentgenographic examination of the esophagus when filled with an opaque substance, maps out accurately the contour of these parts of the heart and aorta.

The abdominal portion of the esophagus is of smaller caliber than the rest of the esophagus. This portion may be somewhat conical in shape, with its base toward the stomach, particularly when a small bolus is temporarily lodged in the esophagus between the level of the diaphragm and the stomach. Roentgenographically and anatomically (Moser) the esophagus at the hiatus esophageus of the diaphragm often shows the impression of the left crux of the diaphragm. The so-called cardiospasms involving the esophagus are not limited to the junction of the stomach and esophagus, but extend throughout the lower end of the esophagus from the cardiac orifice to a point about one-half inch above the left crux of the diaphragm.

The esophagus has five coats—an internal or mucous coat, a muscularis mucosæ, a submucous coat, a muscular coat, and an external or fibrous coat (see Fig 21). The mucous coat is covered throughout with a thick layer of stratified pavement epithelium. Between the mucosa and the submucosa is the muscularis mucosæ, a layer of longitudinally arranged smooth muscle tissue. The submucosa is a loose areolar connective tissue which connects loosely the mucous and muscular coats. The esophageal glands, which lie in the submucosa, are small compound racemose glands of the mucous type. The muscle coat (muscularis propria) is composed of two layers of smooth muscle of considerable thickness. The muscle fibers of the inner layer are arranged circularly, and the fibers of the outer layer are arranged longitudinally.

When empty, the esophagus is contracted and its anterior and posterior walls come in contact. The inelastic mucous membrane folds longitudinally (Fig 33), so that on transverse section the lumen of the contracted esophagus is stellate in form (flattened anteroposteriorly).

Roentgenographic examinations have shown that the esophagus normally

does not contain air. However, we not infrequently observe, when a bolus of barium paste is swallowed, that a cylindrical bubble of air is forced down ahead of the bolus. This bubble of air may pass into the stomach, or, after reaching the lower end of the esophagus, the air bubble may pass up along one side of the barium (Figs 22 and 23). It is important not to consider these air bubbles as filling defects in the wall of the esophagus. The shift in position of the air bubble is usually sufficient protection against an erroneous interpretation.

Partial herniation of the stomach through the hiatus esophageus is a not infrequent anomaly, and a persistent air bubble in the digestive tract just above the left crux of the diaphragm is usually due to this condition.

Anatomy of the Stomach.—For the sake of simplicity of description, the stomach may be considered as divided into four chambers, the fornix, corpus, antrum, and cap, by three partitions, the pyloric valve, sulcus angularis, and corporic shelf. This is somewhat similar to Forssell's division of the stomach. Each of these regions will be considered, in the order named.

Fornix.—The fornix is indicated in the schematic drawings (Figs 26 and 27) by horizontal parallel lines. For the purpose of roentgenologic exploration, it may be filled with air or barium. When filled to complete distention, it conforms with the dome of the diaphragm, an excellent reason for terming this region the "dome" of the stomach. This conveys its shape to every one wherever the English language is spoken, whereas most of us must turn to the dictionary for the origin, or meaning, of the term "fornix".

Corpus.—The corpus, or body, of the stomach is indicated by vertical parallel lines in Figures 26 and 27. It is the largest and most distensible chamber of the stomach. With the patient in the erect posture it forms a vertical column, the right side of which extends from the esophagus to the sulcus angularis, and the left side of which extends to the most dependent portion of the greater curvature. When completely filled, the corpus is free of rugae; when it is empty, or partly filled, the mucosa is thrown into folds or rugae (Figs 33, 34, and 35).

Antrum.—The antrum is indicated in Figures 26 and 27 by oblique parallel lines, and is that portion of the stomach between the sulcus angularis and the pyloric valve. When distended it is egg-shaped, with the small end of the egg lying toward the pyloric valve, and it is free of rugae, so that the mucosal surface, as observed roentgenographically, is smooth. During a short period of each gastric cycle the distal end of the antrum is contracted by the fan-shaped pyloric muscle into a pyloric canal, which is indicated by cross-hatching in Figure 27. During this period the mucosa of this region is thrown into characteristic folds.

Cap.—The cap, which we shall subsequently consider as a separate organ, may be included here as a fourth chamber of the stomach. (It is indicated by dots in schematic Figures 26 and 27.) It is bounded proximally by the pyloric valve, and distally by the first of the valvulae conniventes that are so characteristic of all portions of the small intestine. When the cap is distended it corresponds in size and shape to the pyloric antrum and sets upon the latter.

like a brimless cap, or *beret*. If the partition between the antrum and cap is obscured by a pencil, the significance of the cap, as relating to the stomach rather than to the small intestine, becomes apparent. When the cap is distended it is singularly free of rugæ, when contracted, its mucosa has a characteristic appearance. The mucosal pattern of the cap is somewhat similar to that of the stomach, but it differs radically from that of the duodenum and all other portions of the small intestine.

Pyloric Valve.—On roentgenologic exploration, the lumen of the cap is found to be separated from the lumen of the antrum by a clear-cut, well defined space about 3/16ths of an inch (0.5 cm.) in length (longitudinal axis of the gut). The length of this space may vary slightly with different cases and with different phases of the cycle of gastric peristalsis, but it is one of the most definite findings in the entire gastro-intestinal tract, and, roentgenologically, is the monumental landmark from which to measure in either direction. It serves as one of the best illustrations for the demonstration of our second fundamental finding, namely, the muco-membranous fold viewed on edge (Figs. 31, 37, and 52).

Sulcus Angularis.—The antrum is separated from the corpus by a less definite partition located at the point of the *incisura angularis*. This partition, although varying considerably in length, is markedly constant in its thickness, as illustrated by Figures 32 and 51. This partition also serves to illustrate the second fundamental finding. The base of the *sulcus angularis* is opposite the receding angle or *incisura angularis*, which may be observed on the outside of the stomach.

Corporic Shelf.—The corpus is separated from the fornix by a less definite partition, the corporic shelf, that occurs about on a level with the esophageal orifice (Figs. 28 and 29). This corporic shelf is not a constant roentgenologic finding.

Variation in Shape of the Stomach during a Single Cycle of the Complex Gastric Motor Phenomenon.—The stomach goes through a series of shapes and comes back to its original shape about once in twenty seconds. This recurrent series of events is known as a "gastric cycle," ten stages of which are shown in Figure 30. The gastric cycle, like the cardiac cycle, has a systolic and diastolic phase. Likewise, similar to the asynchronous systole and diastole of the auricles and ventricles of the heart, there is an asynchronous systole and diastole of two divisions of the stomach, the first of these functional divisions being the corpus and the proximal part of the antrum, and the second being the pyloric canal. During systole of the first or superior division, termed "systole of the stomach," peristaltic waves of contraction form, and simultaneously the contractions become deeper and progress toward the distal end of the stomach. During *early diastole* the waves of contraction continue to progress distally, but they gradually become more and more shallow, until in *mid-diastole* each wave of contraction disappears or becomes most shallow after having progressed distally to the point of origin of the neighboring wave. During the *latter half* of diastole the peristaltic contractions are at their minimum.

Systole and diastole of the pyloric canal is a function of the fan-shaped pyloric muscle. During systole this muscle contracts concentrically to the long axis of the pyloric canal. At the onset of diastole, relaxation of this muscle is rapid and causes the appearance of the anti-peristalsis described by Alvarez. Systole of the pyloric canal occurs during the period of diastole of the upper division of the stomach, and diastole of the pyloric canal occurs just after the onset of systole of the upper division. Two of the ten phases of the gastric cycle have been selected to illustrate the lumen of the stomach—one with the upper division of the stomach in systole (Fig. 31), and the other with the pyloric canal in systole (Fig. 32). These are also illustrated in the line drawings in Figures 26 and 27. Approximately one and one-half gastric cycles are recorded in the roentgenocinematographic series, Figure 15.

Small Intestine.—The small intestine begins at the first plica circularis observed in the duodenum and terminates at the ileocecal valve. There are two main divisions of the small intestine (1) the duodenum, which is largely retroperitoneal in position and relatively fixed, (2) the mesenteric small intestine, which is interperitoneal and, because of its mesentery, relatively movable.

On the basis of relative differences in the mucosa the mesenteric small intestine has been further divided into the jejunum, which is proximal, and the ileum, which is distal. Although the difference in the mucosa of the proximal part of the small intestine and the distal part of the small intestine is marked, there is no abrupt dividing line and the transition from characteristic jejunum to characteristic ileum is gradual. This division of mesenteric small intestine into jejunum and ileum does not, apparently, have a good anatomical basis. Most anatomists prefer to speak of this part of the small intestine as a unit, calling it either the jejunum-ileum or, preferably, the mesenteric small intestine.

During a detailed roentgenographic study of the small intestine, a report of which was published in 1927, we had noticed in the great majority of individuals that the small intestine was arranged in a definite pattern of groups of coils. We were not satisfied with the usual classification of the small intestine into jejunum and ileum because of the absence of any sharp difference between those regions of the small intestine which are supposed to show the greatest variation, namely, the small intestine near the duodeno-jejunal flexure, and the small intestine near the ileocecal valve. We were considering a division of the small intestine according to its arrangement into groups of coils when we learned that such a classification was entirely logical, in that the small intestine develops in the embryo in this manner, and at a very early stage of development shows this typical arrangement into groups of coils. At this time we had not recognized that the loops of the duodenum represented part of this general arrangement. C. M. Jackson, in his section on the digestive system in Morris's "Human Anatomy," states as follows: "Even in an embryo of 19 mm., while the intestine is still in the umbilical celom, Mall described six primary coils of the small intestine which could be usually identified even in the adult. In the adult, as also through the various stages of development, Loop 1 forms the duodenum." From our own studies

we believe that the groups of intestinal coils developing from these six primary coils can be recognized roentgenographically (Fig 38). The first loop (Fig 39) is the duodenum and should be known under that name. The second, third, fourth, fifth, and sixth groups of coils are the mesenteric small intestine. We believe that these several groups of coils can be recognized roentgenographically and that any roentgenologic division of the mesenteric small intestine should be on this basis of development.

Duodenum.—We consider that the duodenum begins at the first crescentic or annular fold of the mucosa distal to the cap, and extends to the duodenjejunal flexure. The duodenum is relatively fixed in position in the form of a loop, the opening of the loop facing to the left and superiorly. The concavity of the loop encircles the head of the pancreas and corresponds in size to it. There are several normal shapes of the loop of the duodenum. Depending upon the relative position and angulation of the superior, descending and inferior parts, the duodenum may be shaped like the capital letters "C," "V," or "U," or may be almost rectangular in shape.

The superior or first part of the duodenum, not the cap, is not retroperitoneal and is usually short. It is best visualized in the right oblique projection (Fig 48). This superior part of the duodenum passes from the distal end of the cap posteriorly and usually superiorly and to the right. The angle at the inferior margin of the junction between the cap and superior duodenum may be obtuse or acute. The more the stomach is raised upward and forward by the abdominal contents, the more obtuse is the angle. In marked elevation of the stomach or in the short typical hypersthenic type of stomach, the cap may point inferiorly into the superior duodenum. This is inversion of the cap. The superior duodenum may be long and occasionally forms a loop inferiorly (Fig 48), the cap and the upper end of the descending duodenum forming the two points of suspension. The folds of the mucosa within the short superior duodenum are usually low in height and few in number. This relative absence of folds is particularly noticeable when the superior duodenum is long and redundant. The superimposition, partial or complete, of a redundant superior duodenum over the cap, as occurs in the anteroposterior projection, produces an irregular shadow which may closely simulate a deformity of the cap due to ulcer (Fig 47).

The descending and inferior parts of the duodenum are relatively fixed in position. This fixation is, however, more relative than absolute, and the position and form of the duodenum usually differ in the prone and erect postures of the individual. The anterior and lateral walls of the duodenum are covered by peritoneum, protrude into the peritoneal cavity, and are relatively free. For this reason the contour will vary considerably with varying degrees of filling. The transverse mesocolon crosses the middle of the descending duodenum, and at this level one not infrequently sees deformation and angulation of the descending duodenum (Figs 49 and 50). This is a congenital malformation acquired at the time that rotation and fixation of the colon occurred.

Duodenjejunal Flexure.—This is usually the highest fixed point of the

small intestine. The inferior duodenum usually ascends to the flexure. The flexure is suspended by the fibromuscular ligament of Treitz which passes down behind the pancreas from the lumbar part of the diaphragm. Very rarely one finds an abnormal location of the duodeno-jejunal flexure, in which case fixation has usually occurred lower in position, somewhere along the normal course of the inferior duodenum.

The intestine is only occasionally held to a point at the duodeno-jejunal flexure. Usually it makes a moderate curve on itself, and less commonly the curve is very wide. The curve at the flexure is usually from posterior to anterior, and for this reason, in many individuals, the angle of the curve can be appreciated best when it is viewed in the oblique or lateral direction. From the duodeno-jejunal flexure the intestine passes forward and usually inferiorly toward either the right or left side. This first loop of the mesenteric small intestine is more commonly directed inferiorly, or inferiorly and to the left, than it is toward the right side. Occasionally the intestine, a short distance distal to the flexure, is caught up at a second point of fixation, forming a short loop.

Mesenteric Small Intestine.—The second group of coils, which forms the first part of the mesenteric small intestine, is usually located in the left hypochondrium and the loops may ascend above the level of the duodeno-jejunal flexure (Fig. 40). The third group of coils is usually located in the left lumbar region and the loops may descend below the plane through the level of the superior iliac spines (Fig. 41). Almost uniformly, both of these groups extend slightly beyond the right side of the spine. It is uncommon, however, to observe several loops of these groups in the right hypochondriac regions. The various loops of these groups are usually quite discrete, particularly when they are widely distributed in the abdomen. Only when they are confined within a relatively small area are they massed together so that the individual loops cannot be recognized.

The fourth group of coils is usually found in the umbilical and upper hypogastric regions (Fig. 42). The fifth group of coils is usually observed in the right lumbar region (Fig. 43) and the sixth group of coils is usually located in the right iliac fossa and the false pelvis, or lower hypogastric region (Figs. 44 and 45). Distinct visualization of the separate loops of the fourth, fifth, and sixth groups largely depends upon their position in the abdomen. If most of the loops are out of the pelvis, they can be individually recognized. When the loops are grouped together in the pelvis they may be so massed together that it is impossible to recognize their outlines. Upward displacement of the intestines by a filled urinary bladder also tends to mass the loops together. This tendency in many individuals for the groups of coils to be massed together is the most serious obstacle we have encountered in attempting accurately to visualize the small intestine.

There is also a characteristic arrangement of the intestinal loops within the groups of coils. In the second and third groups of coils the individual loops lie transversely in the abdomen, and in the fourth, fifth, and sixth groups the individual loops lie vertically. Between each group of coils a rela-

tively longer loop of small intestine extends back to the root of the mesentery. This formation is most characteristically seen between the second and third groups of coils (Figs. 39 and 40).

Displacement of the first and second groups of coils into the right hypochondrium and lumbar region is the rule in association with incomplete rotation of the colon. Rarely it occurs as an isolated abnormality. In both instances the duodeno-jejunal flexure may be displaced out of its usual position. Another unusual anomaly is to have the upper loops of the mesenteric small intestine festooned across the upper abdomen.

The surface of the mucosa of the small intestine is characterized by the presence of numerous circular, spiral, and crescentic folds. These folds, which are most commonly called the *plicae circulares*, are found throughout the small intestine but are most numerous and of greater height in the duodenum and first loops of the mesenteric small intestine. They diminish somewhat in height and number through the fourth and fifth groups of coils. In the sixth group of coils they are short and less numerous and may be absent in the terminal part. The folds are possibly of two types: (1) the permanent folds, that is, those which persist during distention of the intestine and persist in the anatomical specimen (these are a duplication of the mucosa and muscularis mucosæ, bound together by the submucosa), (2) those folds which are due to temporary contraction of the muscularis mucosæ. Forssell has called attention to the varying form of the folds of the duodenum and ascribes this to varying contraction of the muscularis mucosæ. More recently Forssell has brought forward a more complicated theory regarding the movements of the mucosa which shall be discussed at a more appropriate time.

Caliber of the Lumen of the Small Intestine—In the living subject the intestine is normally in a state of tonic contraction—it is contracted on itself or its contents. For this reason the caliber of the lumen of any section of the small intestine will depend largely upon the degree of filling or distention. Certain normal variations in the rapidity of emptying of the stomach and the rapidity of passage of the meal through the small intestine will, therefore, modify the distribution of the meal and the appearance of the intestine. Rapid uniform emptying of the stomach will give a large caliber to the intestine throughout the entire length in which the meal is present. With slow or moderately rapid emptying of the stomach the caliber of the lumen of the intestine will be small or moderate, if the passage of the meal through the intestine keeps pace with the emptying of the stomach. If the passage of the meal through the intestine is more rapid than the entrance of the meal into the intestine, the caliber will be small, but usually uniform. If the stomach empties itself intermittently, the distribution of the meal and the caliber of the small intestine will be irregular.

Ileocecal Valve—The small intestine opens into the colon through the ileocecal valve, usually situated on the left posterior side of the proximal end of the colon, and marking the dividing line of the cecum and ascending colon. The valve has two lips, one superior and one inferior. From the anterior and posterior margins of the valve, where the lips meet, a fold (frenulum) which

protrudes into the lumen of the gut, extends partially around the inside of the colon. The indentation of the barium column produced by these folds is not infrequently observed in the roentgenograms of this region. The roentgenographic appearance of the lumen of the open valve as viewed in the postero-anterior direction is illustrated in Figure 46.

Coats of the Stomach and Small Intestine.—As we stated in a recent communication (1928), dealing with the gross morphology of the living stomach and the microscopic anatomy of the stomach (with some reference to the cap), all portions of the gastro-intestinal tract have been described by anatomists as having five coats, namely, (1) mucosa, (2) muscularis mucosæ, (3) submucosa, (4) muscular coat (composed of two or three layers), and (5) the serous coat. These coats differ in thickness and characteristics in various regions of the stomach. In the small intestine their histologic structures vary in different portions to a less degree than in the stomach. Strangely enough, in the last two decades the cap—although the subject of a great deal of controversy—has escaped an intensive investigation of its gross and microscopic anatomical structure, particularly the peculiarities of structure as compared with those of adjacent regions. In the cap there are only three coats. It is very important to have a thorough understanding of the anatomical characteristics of each of these coats in the various regions.

In the stomach (Fig. 51) the mucosa is packed closely with tubular glands. The muscularis mucosæ is a well defined coat firmly fixed to the bases of the tubular glands of the mucosa, and in places continuous with slips of muscle tissue which extend in between the tubular glands. The submucosa has a loose areolar character, permitting the free movement of the mucosa on the regular muscle coat. It is rich in a vascular network that supplies blood to the mucosa on the one side, and to the muscular coat on the other. The muscular coat is very thin in some regions and extremely thick in others. The serous coat is firmly attached to the muscular coat except on the greater and lesser curvatures, but it is important to note that the serous coat draws its blood supply from vessels totally different from those which provide blood to the underlying muscular coat.

Both the sulcus angularis and the pyloric valve are thin muco-membranous folds which consist of mucosa, the muscularis mucosæ, and submucosa. The thickness at the base of both the sulcus angularis and the pyloric valve is just sufficient to contain two layers of mucosa, two layers of muscularis mucosæ, and a core of submucosa. It is obviously impossible for them to contain the definitely thickened fibers of the circular muscular coat of the stomach. Closure of the pyloric valve is caused by a circular contraction of the muscularis mucosæ (Fig. 52). The pyloric valve is not controlled by any specialized pyloric sphincter derived from the circular layer of the muscularis propria. The circular fibers of the muscularis propria terminate just at the base of the pyloric valve, and during the stage of relaxation the distal edge of this thickened muscle is contiguous with the base of the pyloric valve, but does not project down into the valve.

At the junction of the cap and pyloric valve, that is, at the distal side of

the pyloric valve, there is an abrupt change in all of the coats (Fig 52) The mucosa with its characteristics of the pyloric antrum covers both the proximal and distal surfaces of the pyloric valve, and the antral characteristics of the mucosa terminate suddenly at the base of the cap, where the deep tubules of Brunner's glands replace the bulk of the loose areolar submucosa The muscularis mucosæ terminates abruptly as a continuous layer, and splits up into thin strands which are lost in the connective tissue stroma between the straight superficial stalks of the glands and their deeper convoluted racemose tubules

As compared with the stomach, the muscularis propria of the cap is thin and incomplete It is composed largely of longitudinal fibers which are a continuation of the longitudinal muscle coat of the stomach The circular layer of the muscularis propria of the stomach terminates at the distal end of the thick fan-shaped muscle of the pyloric canal Distal to this there is no circular layer of muscle until about the middle of the cap

The junction of the cap and small intestine (duodenum) is marked by the first annular or crescentic fold (*plica circularis*) distal to the pyloric valve The loose, areolar submucosa and the muscularis mucosæ are re-established at this point, which allows folds of the mucosa to form by contraction of the muscularis mucosæ The number of coats in the small intestine is also five, and they are arranged similarly to those of the stomach, without, however, as stated above, as much variation in their structure

In the cap, therefore, the structure of the wall of the gut differs considerably from the structure of the wall of the stomach and small intestine (Fig 53) The submucosa as a loose areolar structure and the muscularis mucosæ are absent, being replaced by the bulky racemose convoluted glands of Brunner, and these glands lie in direct contact with the inner surface of the muscular coat Because of the absence of a loose areolar submucosa the mucosa is relatively immovable upon the muscle coat The muscularis propria of the cap is relatively thin, particularly in a local region which completely encircles the cap about one-fourth of an inch distal to the pyloric valve In this local region (Fig 52, X) the muscular coat is diminished from 40 to 98 per cent, leaving in some cases only 2 per cent of muscle, according to Howell On the ventral surface of the cap the peritoneum is tightly adherent to the muscularis propria Posteriorly, a space similar to the intraperitoneal gastric triangle is present between the dorsal surface of the cap and the descending duodenum The blood supply of the cap is derived from both the pyloric branch of the right gastric artery and the gastroduodenal artery The branches of both of these arteries terminate in end arteries, (1) in the local region just distal to the pyloric valve where the muscle coat is extremely thin, (2) in the pyloric valve itself, and (3) in the extreme distal end of the pyloric canal just proximal to the valve

It would appear from the peculiar characteristics of this local region of the cap, namely an area from which two coats are absent (muscularis mucosæ and submucosa), where the musculature is thinner than in any other part of the gastro-intestinal tract, where the mucosal glands change abruptly from a

straight tubular to a racemose type of gland, and where the pyloric and duodenal arteries terminate in end arteries, that this region would present findings of more than academic interest. In fact, the anatomical structures in this region form a vulnerable ring or collar which, as indicated by the facts, represents the point of junction of the foregut and midgut during an early embryonic stage of development. The irregularities are those presented by two laminated structures improperly welded together. We regard the findings in this area as not only important from the pathologic, surgical, and roentgenologic standpoints, but also as anatomical factors predisposing to ulcer of the cap, and of great importance in the life history of ulcer of the cap.

The Colon.—The normal colon (Figs. 54-57) may be divided into six easily recognized regions, the cecum, the ascending, transverse, and descending colons, the sigmoid, and the rectum. Each has individual roentgenologic characteristics. There are two important flexures, the hepatic and splenic. The colon almost completely encircles the abdominal cavity from the situation of the cecum in the right iliac region to the situation of the rectum in the middle posterior part of the pelvis. The normal colon of all individuals conforms in general to a definite pattern or type, although every colon is prone to show some slight variation. The length of the colon varies considerably, both absolutely in different individuals and relatively in the same individual, depending upon the degree of contraction and relaxation of the colon. When the length of the colon is absolutely increased over the usual normal, the increase may be evenly distributed over the various divisions of the colon, but it is more usual for the increase in length to be limited to one or two divisions.

As regards the usual location of the various divisions of the colon, the cecum lies in the right iliac fossa. The ascending colon extends upward from the cecum along the right side of the posterior wall of the abdomen to the under surface of the liver. Here, at the hepatic flexure, the colon bends sharply forward and to the left. The next division, the transverse colon, extends to the splenic flexure. The transverse colon is festooned across the abdomen, suspended by the fixation at the hepatic and splenic flexures and through the gastro-colic ligament and mesocolon, and lies anterior to the small intestine. In the left hypochondrium at the splenic flexure the colon bends sharply posteriorly and inferiorly, from which point the descending colon passes inferiorly, lying along the left side of the posterior abdominal wall, to the left iliac fossa. There is usually no sharply defined point of transition between the descending and sigmoid colon, and for sake of clearness it is probably best to use the crest of the left ilium as the line of transition, below which the colon is termed the sigmoid colon. At approximately the brim of the true pelvis the sigmoid colon acquires a mesentery and, because it is longer than its mesenteric attachment, assumes the form of a loop. The sigmoid terminates in the rectum just below the promontory of the sacrum at the level of the body of the third sacral segment. The rectum extends inferiorly, following the curve of the sacrum, and at the floor of the pelvis bends posteriorly and passes through the floor of the pelvis as the anus.

The caliber of the colon varies directly with the volume of its contents.

the pyloric valve, there is an abrupt change in all of the coats (Fig 52) The mucosa with its characteristics of the pyloric antrum covers both the proximal and distal surfaces of the pyloric valve, and the antral characteristics of the mucosa terminate suddenly at the base of the cap, where the deep tubules of Brunner's glands replace the bulk of the loose areolar submucosa The muscularis mucosæ terminates abruptly as a continuous layer, and splits up into thin strands which are lost in the connective tissue stroma between the straight superficial stalks of the glands and their deeper convoluted racemose tubules

As compared with the stomach, the muscularis propria of the cap is thin and incomplete It is composed largely of longitudinal fibers which are a continuation of the longitudinal muscle coat of the stomach The circular layer of the muscularis propria of the stomach terminates at the distal end of the thick fan-shaped muscle of the pyloric canal Distal to this there is no circular layer of muscle until about the middle of the cap

The junction of the cap and small intestine (duodenum) is marked by the first annular or crescentic fold (*plica circularis*) distal to the pyloric valve The loose, areolar submucosa and the muscularis mucosæ are re-established at this point, which allows folds of the mucosa to form by contraction of the muscularis mucosæ The number of coats in the small intestine is also five, and they are arranged similarly to those of the stomach, without, however, as stated above, as much variation in their structure

In the cap, therefore, the structure of the wall of the gut differs considerably from the structure of the wall of the stomach and small intestine (Fig 53) The submucosa as a loose areolar structure and the muscularis mucosæ are absent, being replaced by the bulky racemose convoluted glands of Brunner, and these glands lie in direct contact with the inner surface of the muscular coat Because of the absence of a loose areolar submucosa the mucosa is relatively immovable upon the muscle coat The muscularis propria of the cap is relatively thin, particularly in a local region which completely encircles the cap about one-fourth of an inch distal to the pyloric valve In this local region (Fig 52 X) the muscular coat is diminished from 40 to 98 per cent, leaving in some cases only 2 per cent of muscle, according to Howell On the ventral surface of the cap the peritoneum is tightly adherent to the muscularis propria Posteriorly, a space similar to the intraperitoneal gastric triangle is present between the dorsal surface of the cap and the descending duodenum The blood supply of the cap is derived from both the pyloric branch of the right gastric artery and the gastroduodenal artery The branches of both of these arteries terminate in end arteries, (1) in the local region just distal to the pyloric valve where the muscle coat is extremely thin, (2) in the pyloric valve itself, and (3) in the extreme distal end of the pyloric canal, just proximal to the valve

It would appear from the peculiar characteristics of this local region of the cap, namely, an area from which two coats are absent (muscularis mucosæ and submucosa), where the musculature is thinner than in any other part of the gastro-intestinal tract, where the mucosal glands change abruptly from a

over a long area to expel its contents (Figs 58 and 59) The lowest level of the festoon of the transverse colon depends upon several factors (1) the general build of the individual, (2) the length of the transverse colon, (3) the height of fixation of the hepatic and splenic flexures, and (4) the degree of filling of the transverse colon All of these factors must be taken into consideration in determining the possible clinical importance of a low transverse colon One must always bear in mind that the position of certain abdominal organs will depend upon the size, movability, and solidity of the organ itself, and upon the size and shape of the available space which it may occupy An abnormally short transverse colon will press upon the posterior surface of the stomach and produce a cascade type of stomach

Hepatic and Splenic Flexures—We know from the roentgenographic studies of the colon of many individuals by means of the barium meal and the barium enema, and with the colon filled with varying amounts of an opaque suspension, that the degree of fixation and the height of fixation of these flexures is markedly varied, and that the flexures may change position in the same individual The position of the hepatic flexure varies the least both in different individuals and in the same individual Usually it bears a fairly constant relation to the lower surface of the liver, and is displaced inferiorly by enlargement of the liver, both anteriorly and inferiorly by a growth developing in the tissues posterior to it, and by any considerable enlargement of the right kidney

The splenic flexure generally lies at a higher level than the hepatic flexure, but is as a rule more freely movable, and in a few cases lies at a lower level than the hepatic flexure Only rarely is the splenic flexure as high as the diaphragm, and in these few cases there is an abnormally firm fixation of the splenic flexure to the under surface of the diaphragm

Descending and Sigmoid Colon—The descending colon is normally not provided with a mesentery and is quite firmly fixed in position The descending colon follows a fairly straight course and the only common variation is a short anterior looping which is fairly frequently present just above the crest of the left ilium

In the left iliac fossa about two inches below the level of the crest of the ilium the colon is very frequently covered by a peritoneal band which limits the expansibility of this part of the colon (Fig 65) This occurs just above the point where the mesentery of the sigmoid colon begins, and is frequently used as a landmark to establish the division between the descending and sigmoid colon An excellent drawing of an anatomical specimen showing this condition from Piersol's 1911 edition of Quain's "Human Anatomy," is reproduced here (Fig 64)

The form of the sigmoid colon varies more than that of any other part of the colon Its simplest form is a short loop Depending upon its length and the length of its mesentery, it assumes many bizarre forms and occupies various positions It may lie coiled entirely within the lesser pelvis, and yet we have seen a long loop of the sigmoid reach to as high a level as the splenic flexure

The potential caliber is apparently largest in the cecum and proximal part of the ascending colon and the rectum. When the colon is evenly filled with the usual one to two liter (quart) enema, the caliber diminishes gradually from the cecum to the lower part of the sigmoid, and is then increased in the rectum.

Cecum—The cecum is usually covered on all sides with peritoneum. The form of the cecum is variable, the most extreme variation being a long cecum which tapers directly into the appendix. The well filled normal cecum will usually show an indentation at its inferior border corresponding to the site of the anterior band of longitudinal muscle. The cecum most commonly lies in the right iliac fossa, but varies considerably and may lie above the crest of the right ilium or deep in the pelvis. This variation in position is largely due to variations in length of the ascending colon. An abnormally movable cecum, cecum mobile, occurs when the ascending colon is provided with a mesentery. Situation of the cecum on the right side of or posterior to the ascending colon is the result of an incomplete or arrested descent of the cecum. In these cases the appendix is almost always fixed at a higher level than is the cecum.

Ascending Colon—The anterior and both lateral walls of the ascending colon are covered with peritoneum, but the posterior wall lies directly on the fascia over the psoas and quadratus lumborum muscles. There is normally no mesentery. The ascending colon, conforming to the posterior abdominal wall, forms a posterior curve which is best appreciated when the colon is viewed from the side (Fig. 56). When this curve is marked, as is not infrequently the case, a considerable part of the ascending colon may be concealed in the usual anterior or posterior roentgenographic projection.

Congenital veils are very commonly present in relation to the ascending colon. Usually these are broad, thin veils which deform slightly the contour of the colon without producing any stenosis and without limiting seriously the expansibility of this part of the colon. In some instances the veil is not limited to the ascending colon, but extends to the distal loop of the hepatic flexure and the proximal part of the transverse colon, holding the ascending colon and the proximal part of the transverse colon in close apposition and producing a sharp angulation of the colon at the hepatic flexure. Very rarely, instead of a thin, diffuse veil, there will be a narrow, localized, dense band which constricts the colon and causes a definite stasis proximal to the point of constriction. These may be acquired during life due to an inflammatory process, but are more commonly congenital anomalies, probably abnormal fixations of the omentum.

Transverse Colon—The transverse colon, normally slung like a hammock between the hepatic and splenic flexures and attached to the posterior abdominal wall by the long transverse mesocolon, is the most freely movable part of the colon. The transverse colon varies markedly in length in different individuals, and in the same individual shows a marked difference in length at various stages of filling and contraction. In this part of the colon one may see most clearly the shortening of the colon which occurs when it contracts

contractions which originate in the tonically contracted muscle of this tract. A second physiological function is the origin in this tract of waves of contraction which pass distally and convey the fecal contents into the more distal parts of the colon. In our own material we have occasionally observed an area of tonic contraction in this part of the ascending colon (Fig. 62). In one case in particular (Fig. 63) it was a persistent finding and the site of origin of repeated, extensive contractions of the more distal part of the colon, and was, apparently, the functional source of a marked diarrhea which occurred with any worry or excitation. The findings obtained from studies of the colon by means of the barium enema also show that in many cases the contraction of the colon which evacuates the enema begins at this point (Fig. 62). This is most commonly observed and is actually a source of difficulty when one attempts to keep the colon filled with a barium enema before the irritative effects of castor oil have disappeared. From our own findings we are unable to find any positive evidence of a sphincteric action. When the barium meal passes from the small intestine into the colon, it gradually fills the ascending colon in continuity, and is more likely to be carried over into the transverse colon at an early period than to linger in the cecum and proximal part of the ascending colon.

Cannon and other observers have described a normally recurring area of tonic contraction which arises in the proximal part of the transverse colon. In animal experiments, peristaltic waves of contraction which pass both proximally and distally have been observed as originating in this area of tonic contraction. Roentgenologically one quite frequently observes long waves of contraction which originate in the proximal part of the transverse colon and produce a mass movement of the fecal contents which has been described by Case and others. Contractions arising in this region are more frequently observed in the forward passage of the barium meal than in the evacuation of the barium enema. An area of tonic contraction in the proximal part of the transverse colon is illustrated in Figure 61.

A less commonly observed sphincteric tract, which is apparently also a localized tonic contraction, is the rectosigmoid apparatus at the junction of the sigmoid colon and rectum.

(To be continued)

Rectum—The colon becomes fixed in position again in the posterior part of the pelvis at the level of the third lumbar vertebra, and continues inferiorly as the rectum. The rectum is characterized by the presence of three permanent transverse folds, the valves of Houston. One of these is situated on the right side, and the other two are on the left side, one above and one below the right fold. These folds, which are frequently viewed on edge in the roentgenograms, serve to demonstrate the second fundamental finding. At the floor of the pelvis the rectum terminates in its second portion, the anus, which is occasionally observed roentgenographically in the contracted state after evacuation of the barium meal or enema.

The wall of the colon, like the wall of the other parts of the digestive tract, is composed of five coats, namely, mucosa, muscularis mucosæ, submucosa, muscularis propria, and the serosa. This structure is illustrated in Figure 60, which shows one-half of a specimen of the colon cut longitudinally.

This specimen shows also the detailed structure of the semilunar folds which protrude into the lumen of the colon, dividing the lumen into sacculations or haustra. As this figure shows, these folds are composed of a reduplication of mucosa, muscularis mucosæ, and a core of submucosa. In only one region (Fig. 60-A) is there any drawing in of the muscularis propria. It is our conviction, from roentgenographic studies of the colon and from a study of specimens of the colon, that the semilunar folds which form the haustrations of the colon are actively formed by contraction of the muscularis mucosæ, and are not due to contraction of the muscularis propria, and also are not a passive formation due to contraction of the longitudinal bands.

Areas of Tonic Contraction of the Colon—Anatomical and physiological sphincteric tracts have been described in several areas of the colon which have an important bearing in relation to roentgenographic findings. These are not constant formations which can be found routinely in every case, and usually do not have easily demonstrated anatomical characteristics. According to Hirsch they may be recognized in fresh autopsy specimens and on surgical exposure during life as areas of contractions which have a lighter, pinker color than the adjacent areas of the colon. We have observed a similar appearance of the fan-shaped muscle of the pyloric canal. Interesting from a functional standpoint are the experimental findings of Cannon which show that any area of tonic contraction in the colon, whether occurring spontaneously or produced by local stimulation, may act as the origin of waves of contraction which pass distally or proximally from the area of tonic contraction. Spontaneously formed areas of tonic contraction are probably the "pacemakers" of Alvarez.

Hirsch (1924) called attention to the presence of a cecocolic sphincteric tract in the ascending colon about one to two and one-half inches above the ileocecal valve, which he was able to demonstrate roentgenographically and in anatomical specimens. He attributes to this tract the physiological function of retarding the outflow of the cecal contents into the ascending colon until such time as cecal digestion and absorption be complete. He claims that this function is due both to the sphincteric action of this tract and to anti-peristaltic

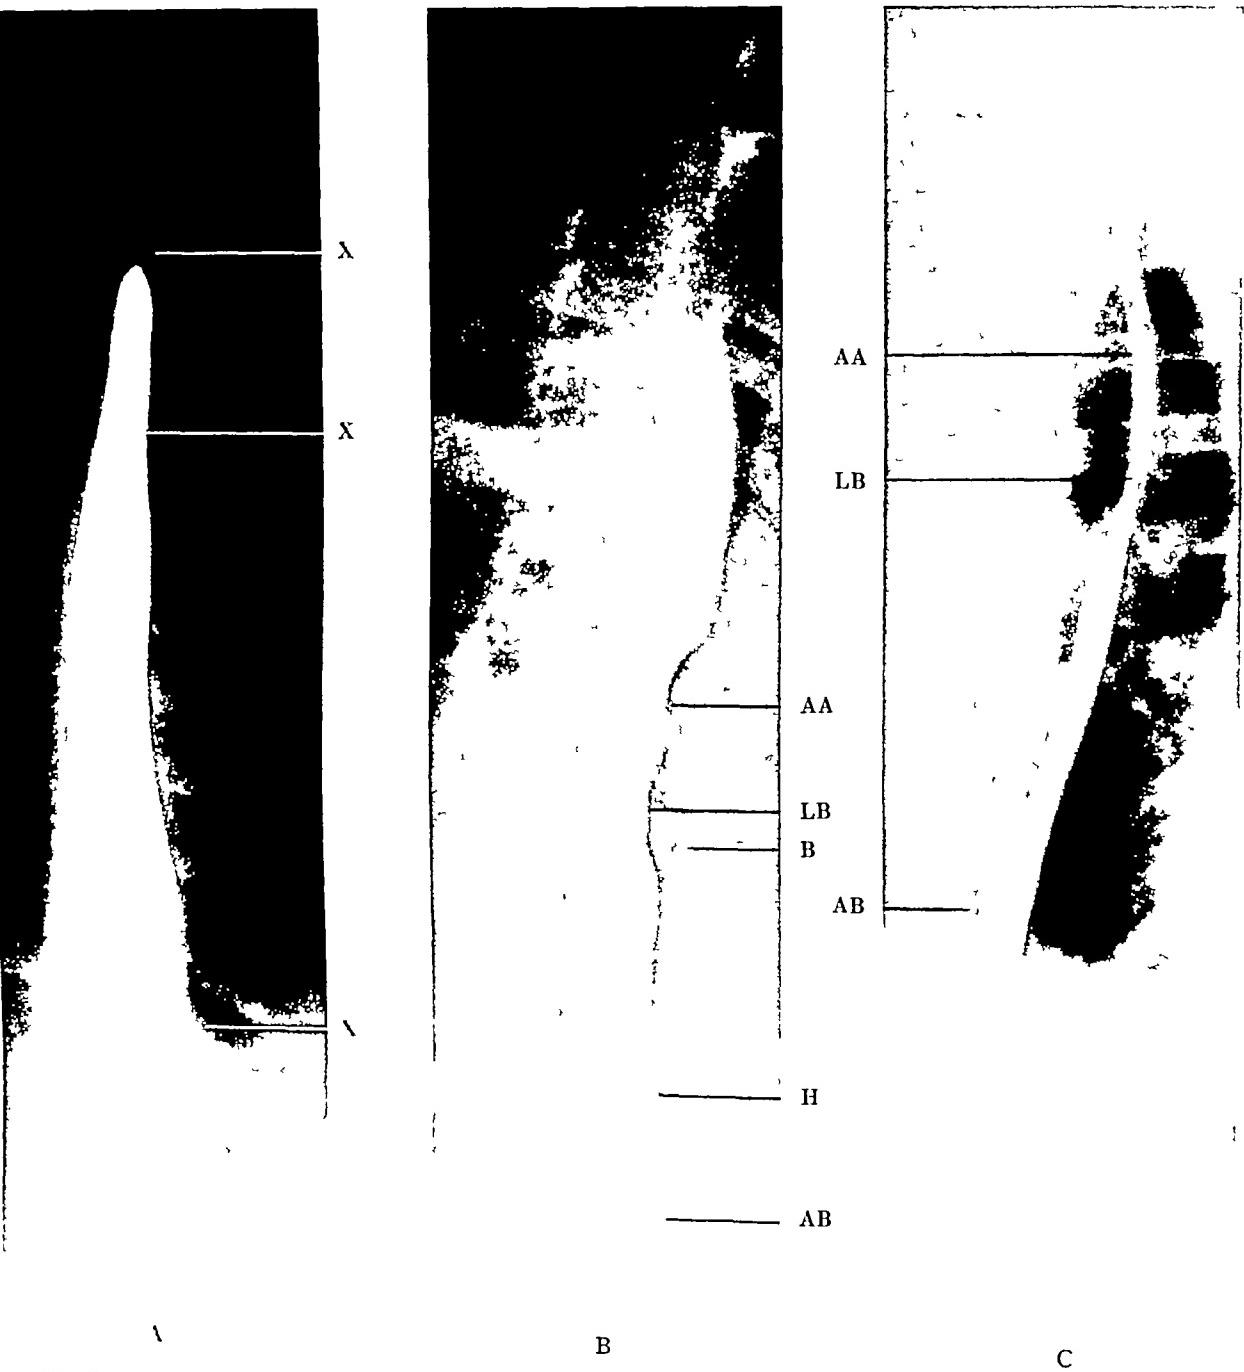

Fig. 20 Roentgenograms made in the anteroposterior (*A*) right oblique (*B*), and left oblique (*C*) projections of the esophagus. The use of these three projections enables one to observe the several profiles of the esophagus exactly as one would step around a tree to observe its curved surface.

A—Indentation of the arch of the aorta. *LB*—Indentation of the left main bronchus (*B*). *H*—Conformation to the contour of the heart. *X*—Anatomical points of narrowing. *AB*—Air bubble.

A and *B* were made with our routine gas tube technic the plate-target distance being 29 inches and the length of exposure 1/20 of a second. *C* was made in 1/40 of a second using a gas tube, 500 milliamperes and a target-plate distance of 42 inches.

Editor's Comment—It may not be amiss to call attention to the unusual excellence of the illustrations which constitute so valuable a part of this series of papers by The Cole Collaborators—Lewis Gregory Cole, M D , Robert Earl Pound, M D , Russell Wright Morse, M D , Courtenay I Headland, M D , William Gregory Cole, M D , and Ames W Naslund, M D These illustrations have been prepared under the close supervision of Dr Lewis Gregory Cole, for whom nothing short of the highest attainable degree of natural similitude has been achieved

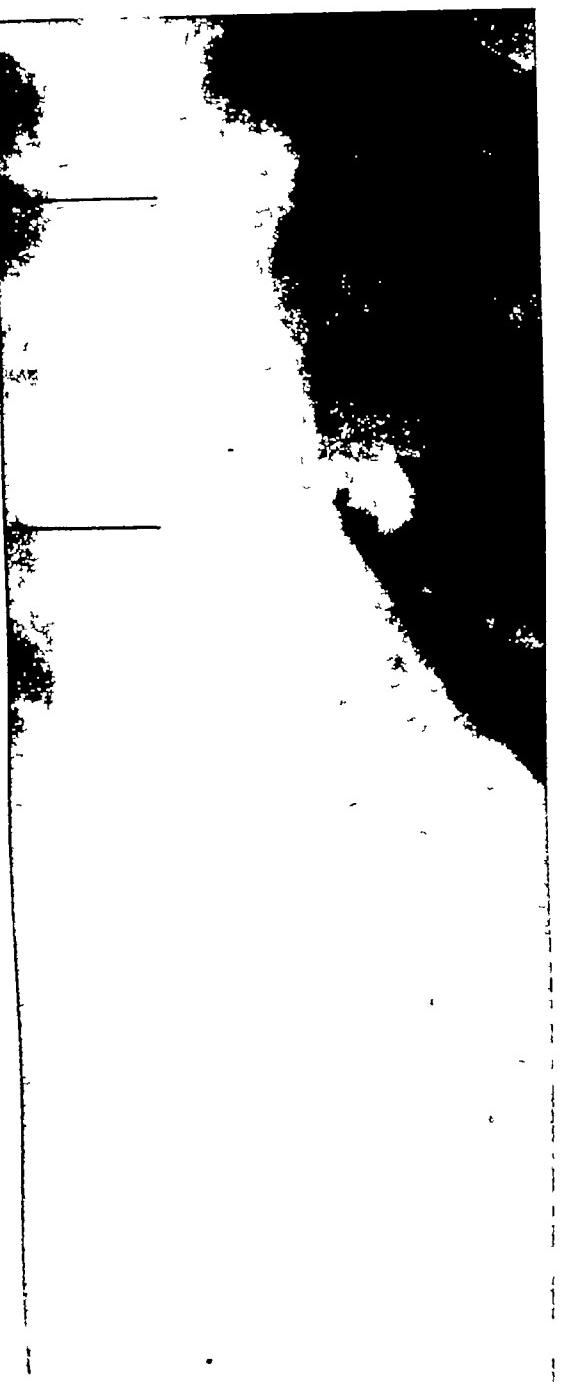

Fig. 22

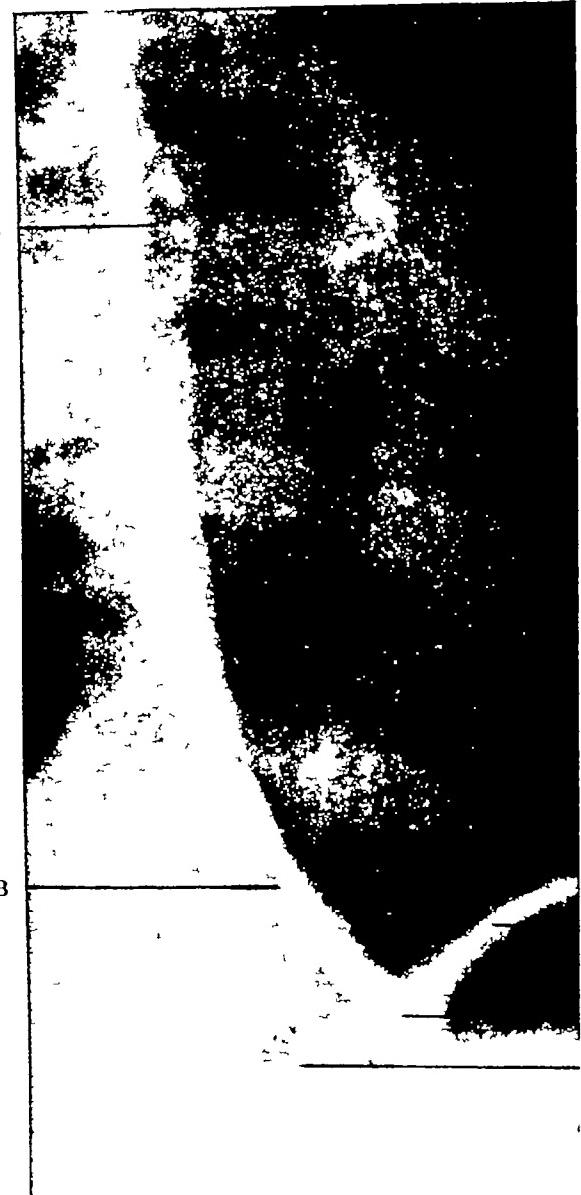

Fig. 23

Figs. 22 and 23 are roentgenograms which illustrate the appearance of air bubbles (*AB*) in the barium-filled esophagus. The air is swallowed and is carried down the esophagus ahead of a bolus of barium. The air either passes into the stomach or, after reaching the lower part of the esophagus, passes upward between the wall of the esophagus and the barium. As shown in these roentgenograms the appearance simulates very closely the displacement of the barium by an organic lesion protruding into the lumen of the esophagus. *AS*-Air bubble in fornix of stomach. *CO*-Cardiac orifice. *D*-Crux of left diaphragm. *F*-Barium adherent to superior wall of fornix. *14*-Indentation of the arch of the aorta.

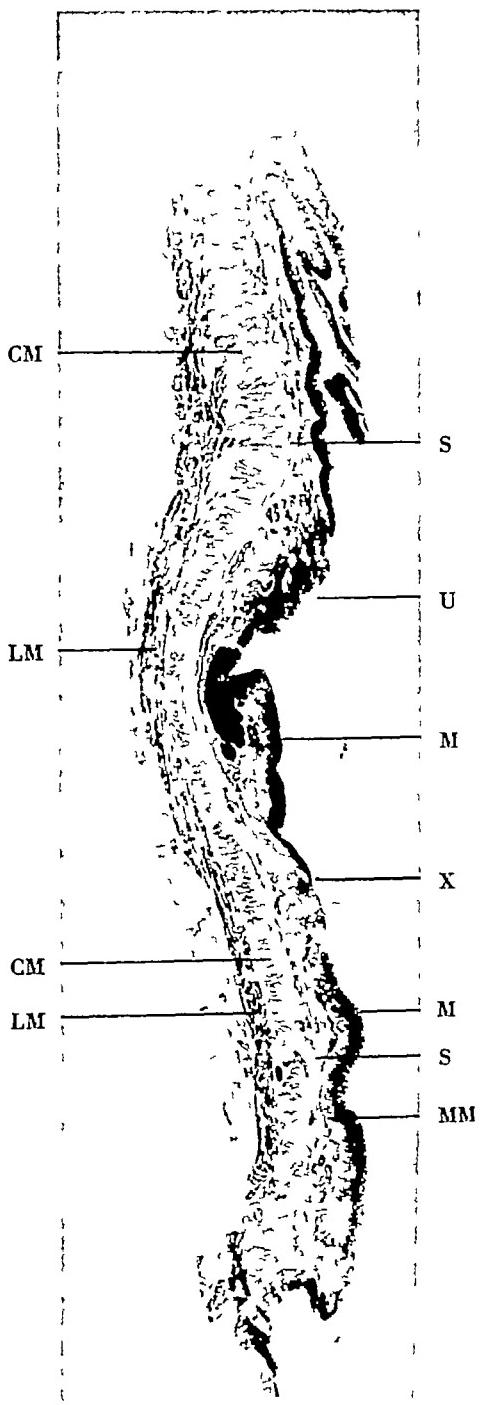

Fig 21 Photomicrograph of a longitudinal section through the lower part of the esophagus and the upper part of the lesser curvature of the stomach. At the junction of the esophagus and stomach (λ), the stained section shows the marked difference in appearance between the stratified squamous epithelium of the esophagus and the tubular glands of the gastric mucosa. There is no break in the structure of the other coats of the esophagus and stomach. At U there is an ulceration of the esophagus involving the mucosa and the submucosa. M —Mucosa. MM —Muscularis mucosae. S —Submucosa. CM —Circular layer of the muscularis propria. LM —Longitudinal layer of the muscularis propria.

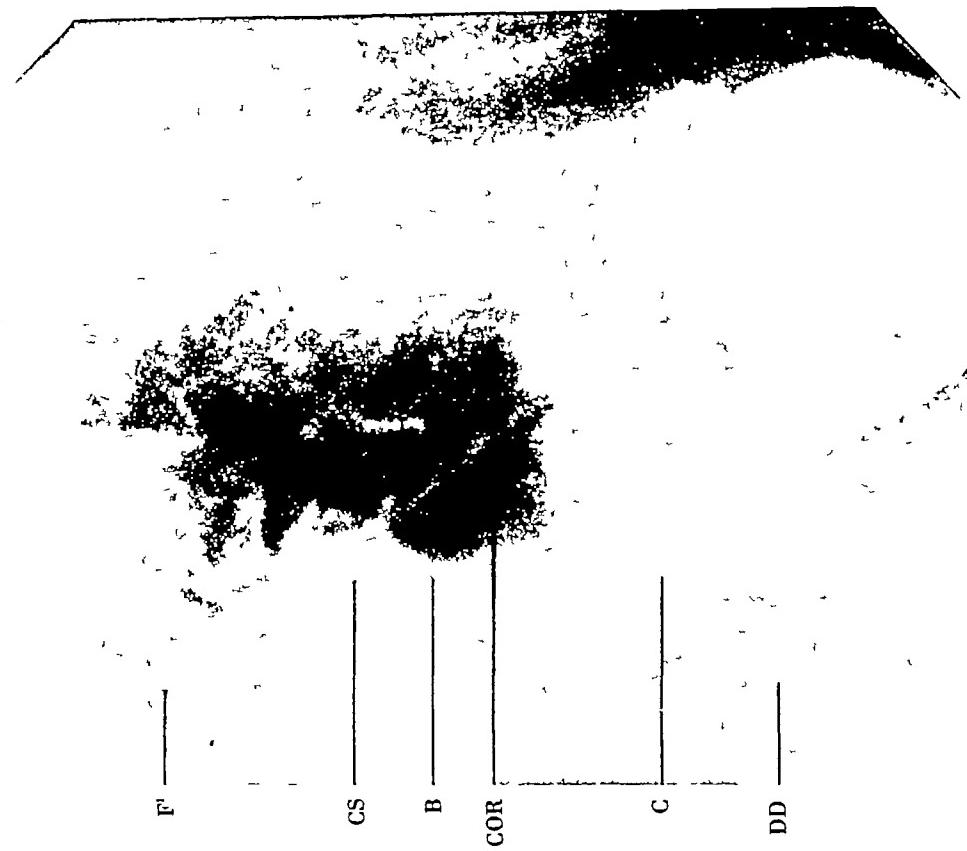

Fig. 29 Right oblique projection, erect posture

Figs. 28 and 29 are roentgenograms of the same individual which show the characteristic findings produced by a well-developed corporic shelf remnant in the oblique projection (Fig. 29, CS). Part of the fornix is at a lower level than the upper division of the corpus and part of the barium meal remains in this lower division of the fornix, as indicated at F' . In the postero-anterior projection the corporic shelf can not be seen, but the characteristic double shadow of barium meal and gas is shown distinctly present in the cascade type of stomach over a high transverse colon (F'). F' —Gas bubble in upper part of fornix. B —Barium in the lower part of the fornix. C —Cap. COR —Corporic shelf. CS —Corporic shelf remnant. DD —Descending duodenum.

C.—Cardia
PC.—Pyloric valve
VC.—Capillary valve
D.—Junction of superior and descending duodenum

Fig. 32

Figs 31 and 32 are roentgenograms which show two stages of the gastro cycle and this is termed "diastole of the pyloric canal." The antrum is fully distended, more or less egg-shaped, and its outline is clear-cut and smooth. The cap (C) is separated from the antrum by the pyloric valve (PV). The base of the cap is wide and corresponds in contour with the adjacent portions of the antrum.

In Fig. 32 the pyloric canal (PC) is in the complete stage of contraction and, therefore, termed "complete systole of the pyloric canal." The barium content of the stomach within this region is evidenced by only a small accumulation of barium between the mucosal folds, which are squeezed together by the strong contraction of the circular fun-shaped muscle. The cap is very narrow at its base, corresponding in contour with the contracted pyloric canal. Compare the appearance of the lumen of the cap as shown in Fig. 36, where the pyloric canal is contracted by rigor mortis of the fun-shaped muscle. Bear in mind that it systole and diastole of the pyloric canal is not the same as systole and diastole of the stomach.

No 1 is the first stage of systole Nos 2 3 4, 5, and 6 are advancing stages of systole No 7 is the beginning of diastole Nos 8 and 9 are relaxing stages of diastole No 10 is complete diastole Nos 7 8 and 9 show concentric contraction of the fan-shaped muscle of the pyloric canal and No 10 shows the sudden relaxation of the fan-shaped muscle

Nos 1 to 10 show progressive filling of the cap during the gastric cycle and Nos 7 8 and 9 show the altered shape of the base of the cap due to the contraction of the fan-shaped muscle

For progression of the peristaltic wave one should note both the greater and lesser curvatures

Fig. 32

Figs. 31 and 32 are roentgenograms which show two stages of the gastro cycle. In Fig. 31 the pyloric canal division of the antrum (*A*) is fully distended and this is termed "diastole of the pyloric canal." The antrum is more or less egg-shaped, and its outline is clear-cut and smooth. The cap (*C*) is separated from the antrum by the pyloric valve (*PV*). The base of the cap is wide and corresponds in contour with the adjacent portions of the antrum.

In Fig. 32 the pyloric canal (*PC*) is in the complete stage of contraction and, therefore, termed "complete systole of the pyloric canal." The barium content of the stomach within this region is evidenced by only a small accumulation of barium between the mucosal folds, which are squeezed together by the strong contraction of the circular fan-shaped muscle. The cap is very narrow at its base, corresponding in contour with the contracted pyloric canal. Compare the appearance of the lumen of the cap as observed here with the outside of the cap as shown in Fig. 36, where the pyloric canal is contracted by rigor mortis of the fan-shaped muscle. Bear in mind that systole and diastole of the pyloric canal is not the same as systole and diastole of the stomach.

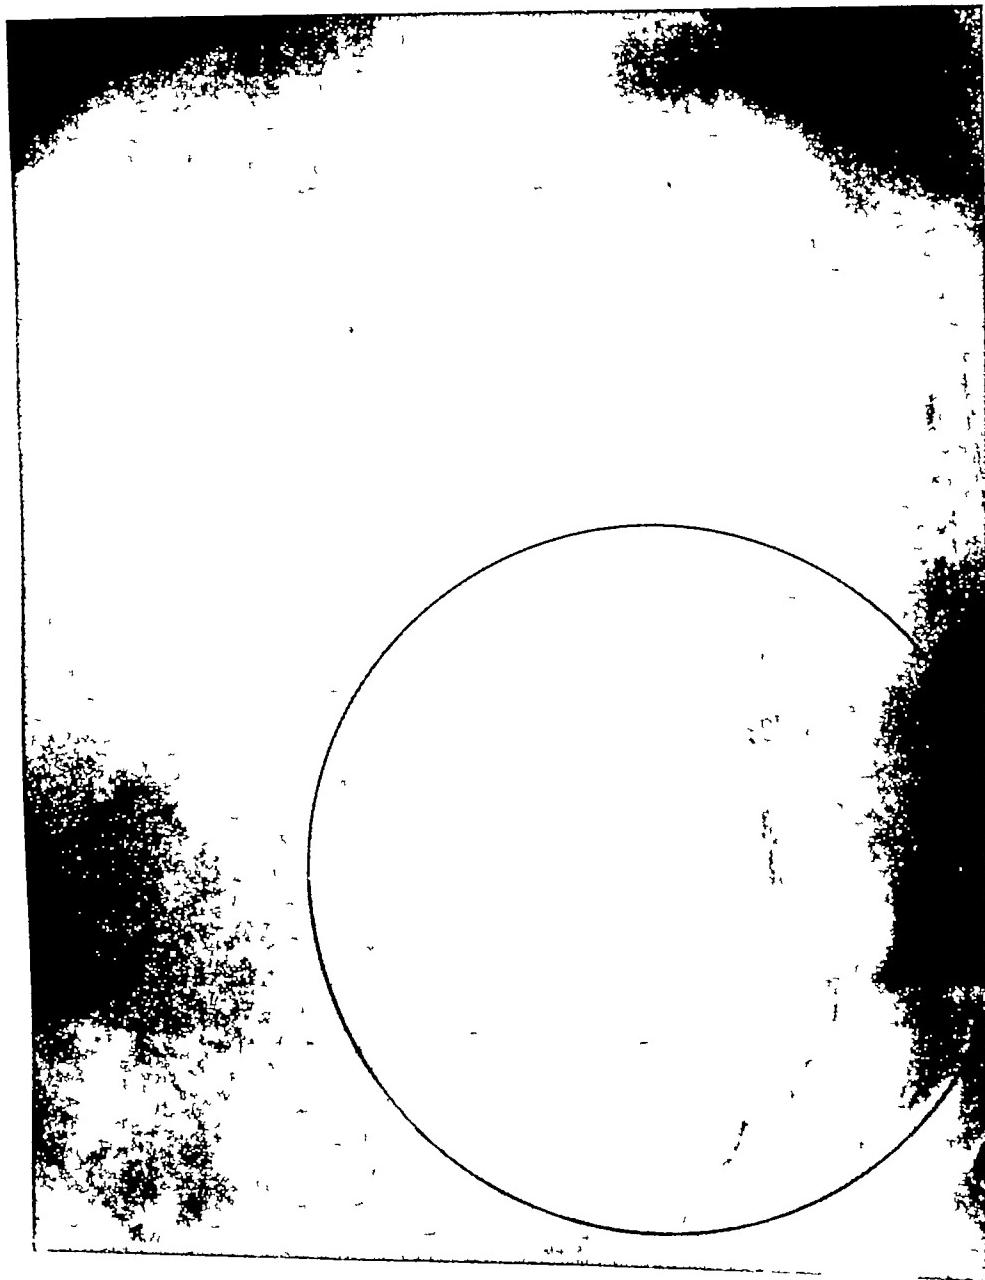

Fig 40. This figure and the following figures are a series of roentgenograms made of the same individual at varying intervals after ingestion of a barium meal. They show the progress of the meal through the small intestine, and the characteristic grouping of the coils of the small intestine.

Patient male, half-hour after the meal. The stomach is emptying at a moderately rapid and uniform rate of speed. The passage of the meal through the small intestine is keeping pace with the emptying of the stomach. All the loops of the small intestine are moderately distended. The circle is around the second group of coils of the small intestine.

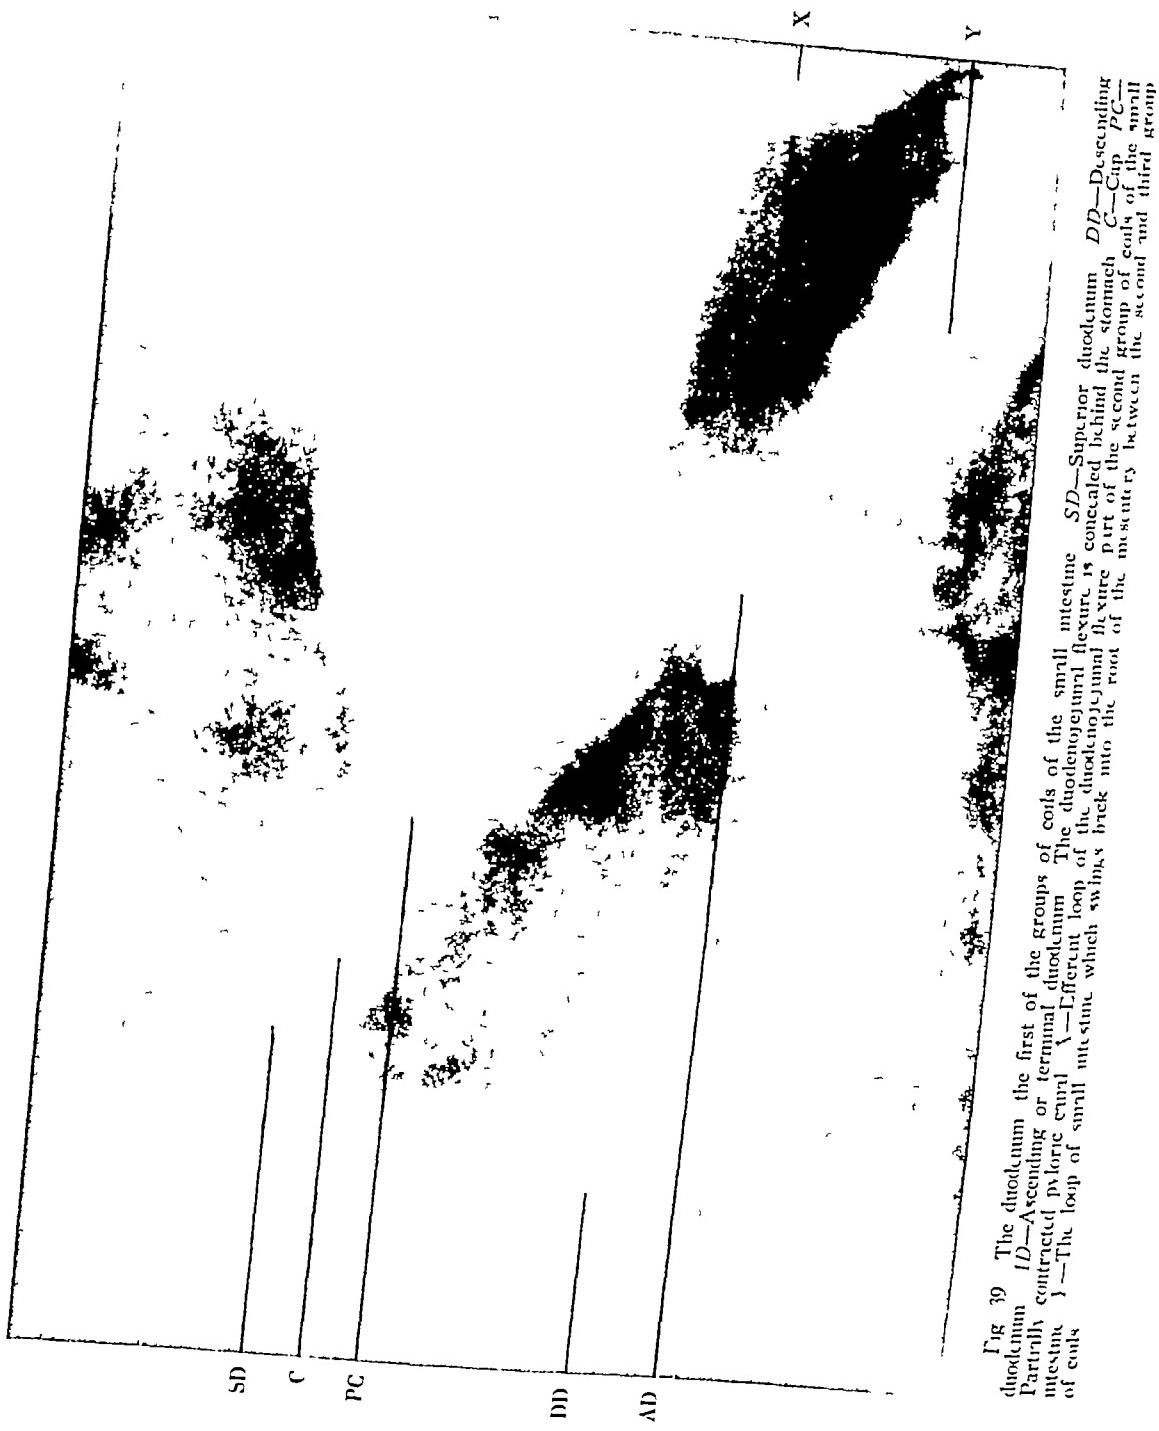

Fig. 39 The duodenum the first of the groups of coils of the small intestine *SD*—Superior duodenum *DD*—Descending duodenum *ID*—Ascending or terminal duodenum *PC*—Descending partially contracted pyloric canal *C*—Cap of the small intestine *Y*—The loop of small intestine which swings back into the root of the mesentery between the second and third group of coils *X*—The duodenocolic flexure behind the stomach *AD*—Descending part of the second group of coils of the small intestine *I*—The duodenojejunal flexure

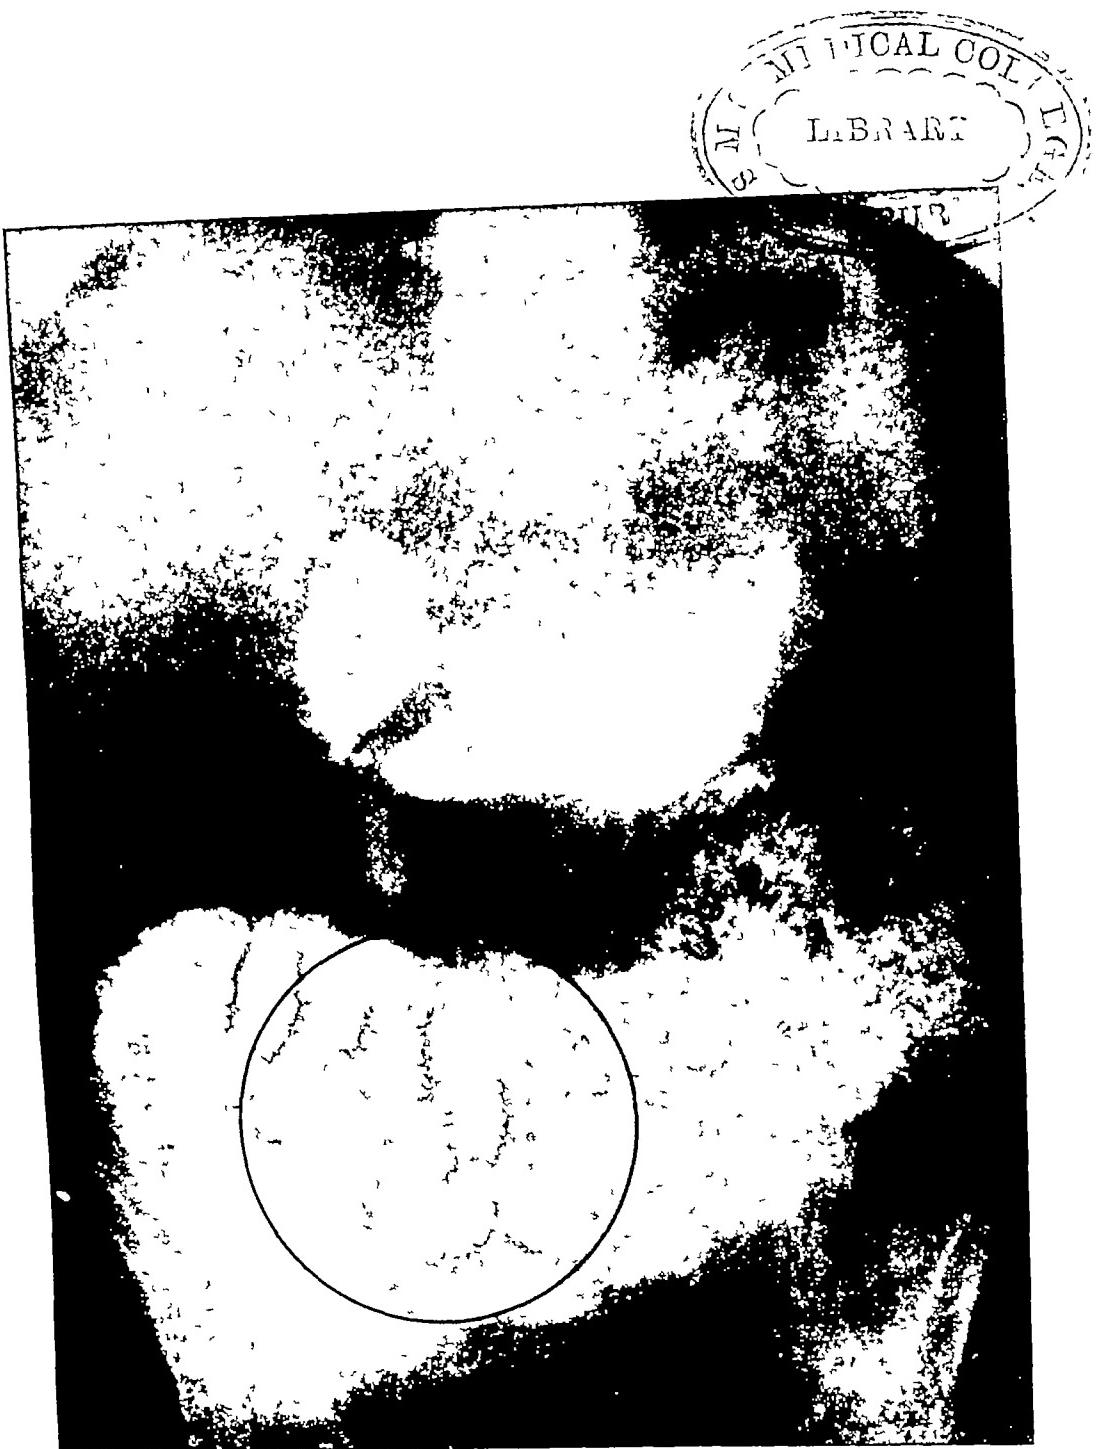

Fig 42 Same case shown in Figures 40 and 41, 2 hrs 10 min after the meal Both the fourth and fifth groups of coils of the small intestine are now filled The circle is around the fourth group of coils The fifth group of coils is to the right of the circle The right iliac and lumbar regions are the usual location of the fifth group of coils

In this figure and the following figures note the vertical arrangement of the coils within the fourth, fifth, and sixth groups of coils, and compare this with the transverse arrangement of the coils in the second and third groups

Fig. 41 Same case shown in Figure 40, one hour after the meal. The second and third group of coils of the small intestine are filled. The circle is around the third group of coils. The loops of this part of the intestine are lower in position and confined more to one region than is usually the case. For this reason the loops overlap and conceal one another. Compare with Figure 38, in which the loops of the second and third groups of coils are discretely shown.

Fig. 44 Same case shown in Figures 40-43, four hours after the meal. The stomach is empty and the head of the column is in the sixth group of coils the location of which is shown by the circle. The lower right iliac and the hypogastric regions and false pelvis are the usual location of the sixth group of coils.

Fig. 43 Same case shown in Figures 40, 41, and 42, three hours after the ingestion of the meal. Most of the barium meal in the small intestine has collected in the fifth group of coils

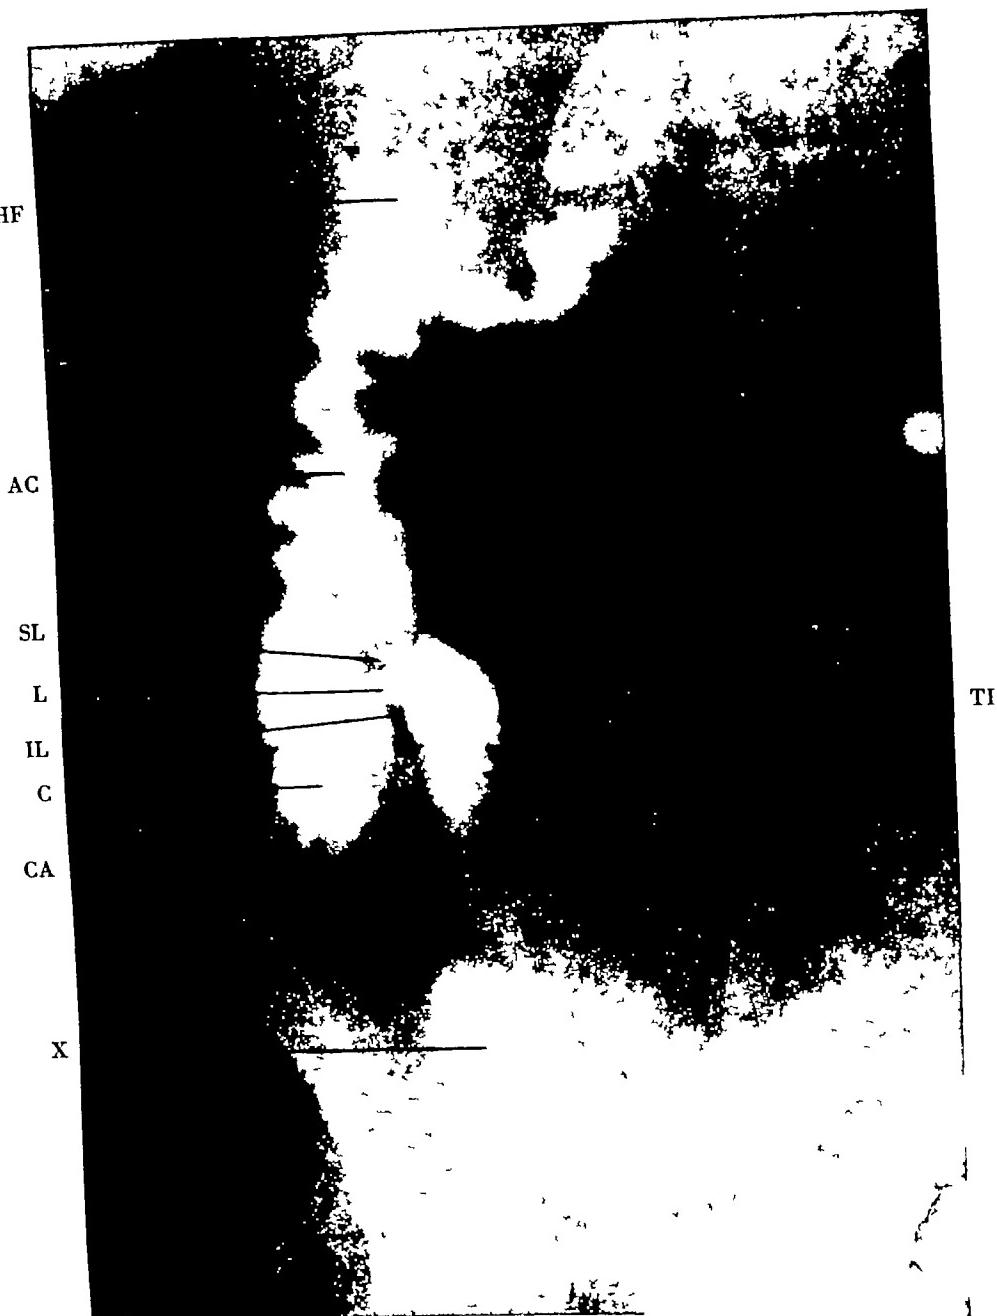

Fig 46 The ileocecal valve as shown roentgenographically immediately after the evacuation of a barium enema. The valve is open. *L*—Lumen of the valve. *SL*—Superior lip of the valve. *IL*—Inferior lip of the valve. *TI*—Terminal ileum. *C*—Cecum. *AC*—Ascending colon. *HF*—Hepatic flexure. *CA*—Area of contraction in the terminal ileum. *X*—Dilated coil of lower ileum proximal to the area of contraction.

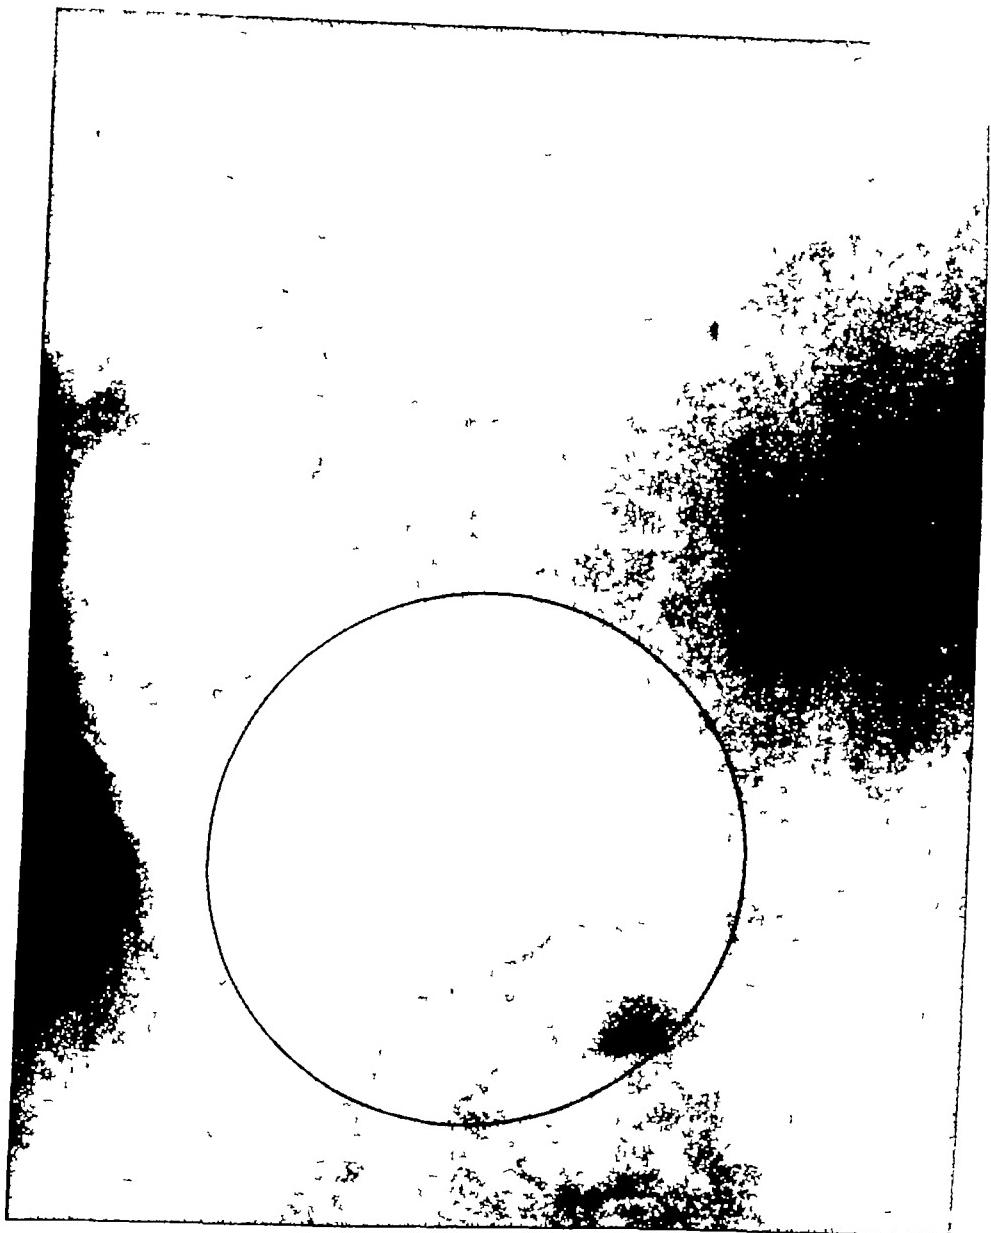

Fig. 45 Same case shown in Figures 40-44, six hours after the meal. The head of the column is at the hepatic flexure. The meal remaining in the small intestine is entirely in the sixth group of coils, as indicated by the circle

Fig. 54

Fig. 55

Fig. 56

Fig. 57

Figs 54, 55, 56 and 57, inclusive, illustrate our routine roentgenographic examination of the colon. In the postero-anterior projection (Fig 54) there is superimposition of regions of the colon at and near both the hepatic and splenic flexures. A lesion of the colon may be concealed in either of these regions. This superimposition of the colon is obviated by making roentgenograms in the right oblique projection (Fig 56), and in the left oblique projection (Fig 57).

The right oblique projection (Fig 56) shows the posterior curve of the ascending colon as it conforms to the curvature of the posterior abdominal wall, and also the sharp curve of the colon at the hepatic flexure.

Fig. 55, the roentgenogram made of the colon immediately after evacuation of the barium enema, shows the colon in the contracted state and the folds of the mucosa.

Fig 58 Colon filled with barium enema

Fig 59 Colon after evacuation of the barium enema

Figs 58 and 59 are roentgenograms made of the same patient, Fig 58 being made when the colon was moderately distended with the barium enema and Fig 59 being made after evacuation of the barium enema. A comparison of these roentgenograms shows the marked diminution in length of the colon which takes place when it is considerably reduced in size and when the stool is evacuated. It is also seen that the sigmoid colon is more easily reduced than the transverse colon.

Fig. 60 Photograph of one-half of a specimen of the colon, cut longitudinally. This specimen was removed by surgical resection and was preserved immediately after removal, the specimen being hardened around a wax cast so that its natural form was retained. *M*—Mucosa *S*—Submucosa *MP*—Muscularis propria *LM*—Longitudinal muscle coat of the muscularis propria *CM*—Circular muscle coat of the muscularis propria *AE*—Appendix epiploica

In this specimen one can observe unusually clearly the structure of the semilunar folds (*F*) which protrude into the lumen of the colon, divide the lumen into sacculations or hastrations, and give to the colon its characteristic appearance. Several of these folds are shown in this specimen and each of these folds is composed of a reduplication of the mucosa and muscularis mucosae and a core of submucosa. The circular layer of muscle of the muscularis propria does not enter into the formation of these folds with the possible exception of the indrawn muscularis propria at $\frac{1}{4}$. It is our conviction from roentgenographic studies of the colon and from a study of specimens of the colon prepared as was this specimen, that the folds which form the hastrations of the colon are due to contraction of the muscularis mucosae and are not due to contraction of the muscularis propria, and are not a passive formation due to contraction of the longitudinal bands.

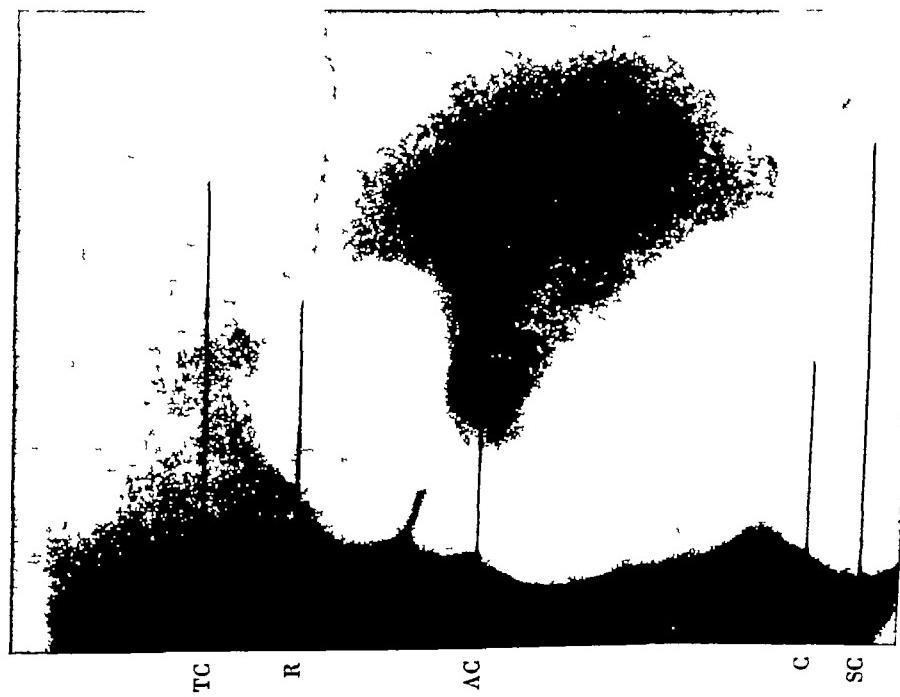

Fig. 61 Ring of tonic contraction (*R*) in the proximal part of the transverse colon (*TC*). The cecum (*C*) and the sigmoid colon (*SC*) are filled with a mixture of the barium enema and fecal material and the density of the shadow is considerably less than that of the barium enema in the transverse colon and the sigmoid colon (*SC*).

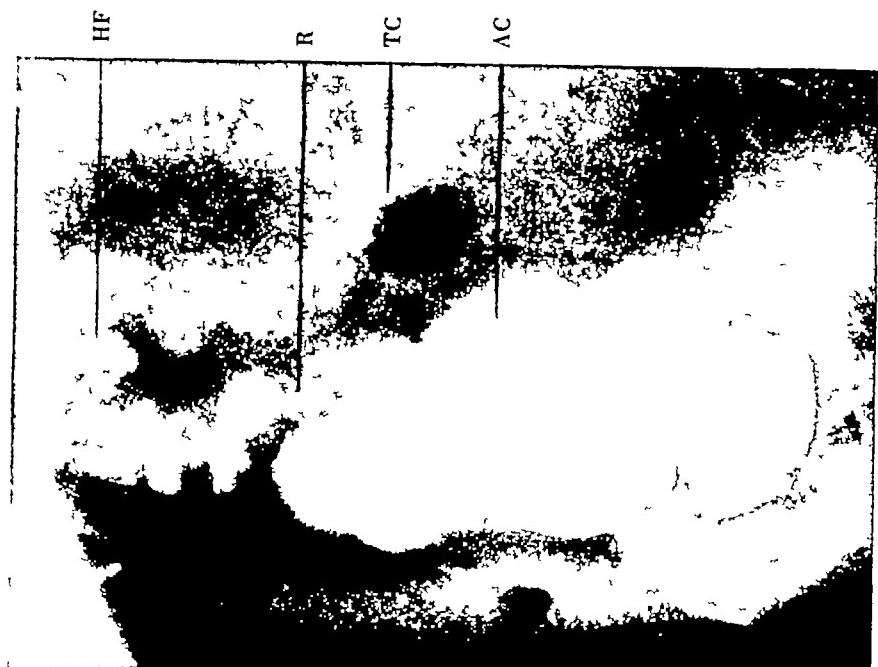

Fig. 62 Roentgenogram made after evacuation of a barium enema which shows a ring of tonic contraction (*R*) in the middle of the ascending colon (*AC*). Proximal to the area of constriction the colon is reflexed and moderately distended. The ring of contraction is at the proximal end of a general contraction of evacuation involving the upper part of the ascending colon (*AC*) and the rectum (*HF* and *SC*).

Fig. 63 Four roentgenograms made of the same individual during an examination of the colon, which show a constant ring of tonic contraction between the cecum and ascending colon. This was apparently a hyperactive pacemaker which was the source of a persistent diarrhea that developed on the least excitation or worry. In spite of the constancy of this annular ring of contraction the presence of normal mucosal folds within the area of contraction demonstrates that it is not due to an organic lesion and enables one to make a negative diagnosis of cancer.

Left side of abdomen, small intestine turned to right, exposing mesentery, mesocolon of descending colon and mesosigmoid. At the junction of the descending and sigmoid colon is labelled in the drawing, the colon is covered with a relatively narrow band of peritoneum. The rectum is shown in its anatomical position in Figure 65.

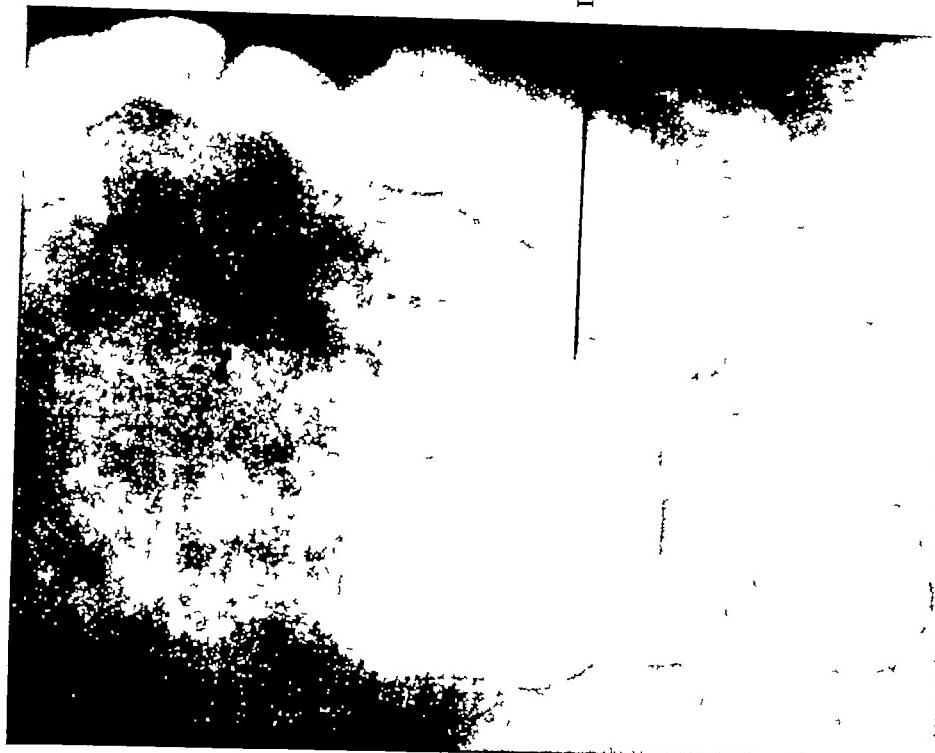

Fig. 65 Roentgenogram showing the descending and sigmoid colon moderately distended with a barium enema. At PB there is fixation of the colon by a band of peritoneum which does not allow the colon to expand as much as the edacent parts of the colon. The anatomical basis for this finding is illustrated in Figure 64.

THE CAPACITY OF X-RAY TUBES AS INFLUENCED BY THE GEOMETRIC DESIGN OF THE FOCAL SPOT, INCLUDING THE ADVANTAGES AND LIMITATIONS OF THE LINE FOCUS PRINCIPLE

By PAUL M ANDRUS, M.D., F.R.C.P. (CAN.), and A HAMBLETON, M.A., B.Sc.,
From the Maris Laboratories at the Queen Alexandra Sanitorium, LONDON, ONTARIO, CANADA

Assisted by the National Research Council of Canada

IT MAY be fairly stated that the capacity of modern X-ray installations is limited only by the ability of the X-ray tube to utilize energy without prohibitive damage. The capacity of the X-ray tube is, in turn, limited largely by its ability to dissipate heat.

The heat-dissipating function of a tube is, however, of two distinct orders. One of these is concerned with the ultimate removal of heat from the anode, as by radiation and conduction. The other is invoked only when much energy is applied in a time interval which is short in terms of the time necessary for conduction of heat by the metal. Under these latter conditions, the tungsten on the immediate surface of the focal spot may be melted while the body of the anode is cold.

Exclusive of the use of a metal having higher specific heat, greater heat conductivity, or higher melting point, we know of only two ways by which the heat capacity of a focal spot may be influenced under large loads of split second duration¹. The first of these is to start the exposure with a cold anode, and, if frequent exposures are necessary, water cooling is a boon to the radiologist for this purpose. The second method is to have the area of the focal spot as large as possible and thus to reduce the load per unit area to a minimum. As a corollary to this, it should be noted that uneven cathode-ray distribution diminishes the effective area of the focal spot by leaving spaces with sub-

average radiation, while overloading adjacent parts.

The ability of a focal spot to utilize energy without damage is, however, meaningless in radiography unless correlated with the degrees of fineness of focus, otherwise we would use therapy tubes for radiography. The area of the focal spot is thus limited by the size of focus we are willing to employ under the conditions in use. Given this limit of size of focus, it is incumbent on the manufacturer to design into the tube the maximum possible focal spot area. This he may do by management of the geometric characters of the focal spot.

The efficiency of an X-ray tube under high-energy, short-exposure conditions, may then be expressed as the ratio of capacity to fineness of focus.² This in turn resolves itself into the ratio of the area of the focal spot to the effective size of the focus under the conditions in use.

It is the purpose of this paper to show the changes that occur in the area of the focal spot, and, consequently, in tube capacity, under varying conditions of focal spot design.

BASIS FOR CAPACITY DETERMINATIONS

Before proceeding to an analysis of varying geometric design, upon the area and consequent capacity of the focal spot, we must first review what is meant by "effective fo-

¹This presupposes that the amount of X radiation reaching the film is constant for any slope of anode. There are apparently, however, no final physical data as to the relation of X-ray intensity in different directions, to the angle at which the cathode stream impinges on the focal spot. In practice, however, we have not observed any reduction of radiation over the film with line focus tubes compared with 45° anodes, providing the tube is placed at the proper distance from the film as shown later in this article.

²The rotating anode constitutes a further principle by which surface capacity may be increased by moving cold metal into the field during the exposure.

FIG 1418

The roentgenographic basis for this finding is illustrated in Figure 64

minor axes of the projection figure is a perfectly satisfactory approximation of the value of the focus at a point [for elliptic focal spots] it is shown in the foregoing communication that this value is more correctly expressed by the average distance between all parallel tangents to the projection figure Since the present study is a theoretic consideration of the efficiency of varying focal spot designs, this latter figure has been used in the derivation of efficiency data)

Technical Methods—The determination of the focal spot area associated with any size or shape of projection figure is, of course, a matter of projective geometry

The determination of the average distance between parallel tangents to any projection figure was made by taking the average distance between parallel tangents at five-degree intervals around the figure Although this may be done mathematically to incorporate all parallel tangents, the methods are too involved to be applicable to this problem In the case of elliptic projection figures (*i.e.*, cast by an elliptical focal spot) the determinations were mathematical In the case of projection figures other than a true ellipse, purely mathematical determinations are, again, impracticable or impossible For these conditions the projection figures were drawn to large scale on co-ordinate paper, and the tangents drawn at five-degree intervals and measured Areas were computed by the method of counting squares

The values given in the tabulations are in each case that area of focal spot which projects unit focus at the cathode end of the film The actual focus is converted to unity by the formula $\frac{\text{Area of Focal Spot}}{(\text{Effective Focus})^2}$ In this way the areas of different designs of focal spot are made directly comparable

The Geometric Shape of the Focal Spot—This resolves itself into an analysis of the relative efficiency of elliptic focal spots *versus* figures of different geometric shape,

but with the major and minor axes of the same size as those of the elliptic focal spots

Such figures are shown in Diagram II in a circumscribed rectangle The larger

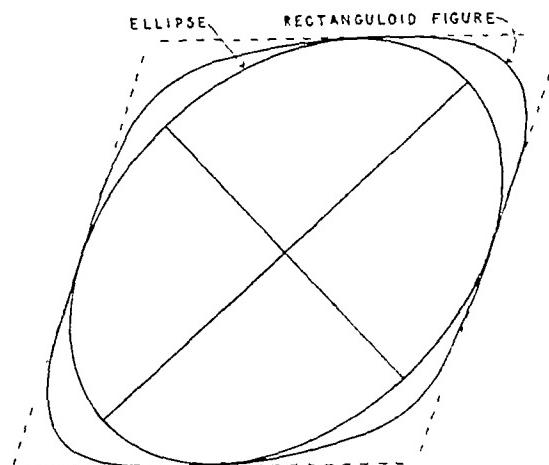

Diagram III. Elliptical and rectanguloid projection figures at cathode corner of film

figure has the shape of the focal spot commonly seen in "line focus" tubes The diagonal of this figure is 83 per cent, and the area is 92 per cent of that of the circumscribed rectangle The area of an ellipse is 78.54 per cent of that of the circumscribed parallelogram The efficiency of this rectanguloid focal spot, as we shall call it, compared with an elliptic focal spot, depends upon which of these geometric shapes has the larger area when both project unit size of focus at the cathode end of the film

TABLE I—AREA OF FOCAL SPOT FOR UNIT FOCUS

| Film Position | Ellipse | Rectanguloid Figure | Gain by Ellipse |
|------------------|---------|---------------------|-----------------|
| Film center | 1.111 | 1.056 | 5.20 per cent |
| Mid-cathode end | 0.804 | 0.770 | 4.42 per cent |
| Mid-anode end | 1.610 | 1.522 | 5.78 per cent |

Mean gain in area by ellipse... 6.39 per cent

Table I shows the area of focal spots, both elliptical and rectanguloid, which project unit focus at various points on a

cus" Focal spot projection, or "focus," is illustrated in Diagram I, and consists of the parallel line projection of the focal spot upon the film An object at any point on a film

the projection figure may be circular, sharpness of shadow will vary in different directions at any given point, corresponding to the varying diameters of the projection fig-

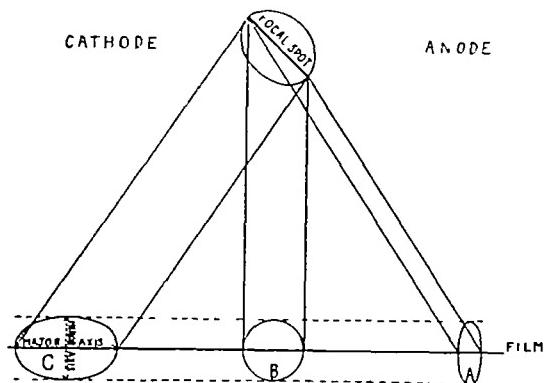

Diagram I Focal spot projection in long axis of tube.

(as at A, B, or C) is, in effect, radiographed with a focal spot of the size and shape of this focal spot projection, and not with the characters of the focal spot itself The "focus" is thus the measure of potential sharpness and radiability on the film as far as the tube itself is concerned Actual sharpness and radiability, of course, depend also on other factors, the chief of which are the ratio of the object-film to the target-object distance, and the excellence of photographic reproduction

It will be seen that the focal spot projection is quite different at different points on the film Identical objects radiographed at the points A, B, and C will consequently cast shadows of quite different characteristics Sharpness of shadow will depend on, *i.e.*, be inversely proportional to, the diameter of the projection figure in any direction, and there will be a varying degree of distortion in the shape of the image at different film positions Since the dimensions of the projection figures become smaller as we proceed from the cathode to the anode end of the film, it follows that sharpness of shadow will also improve in this direction In addition except at the center of the film where

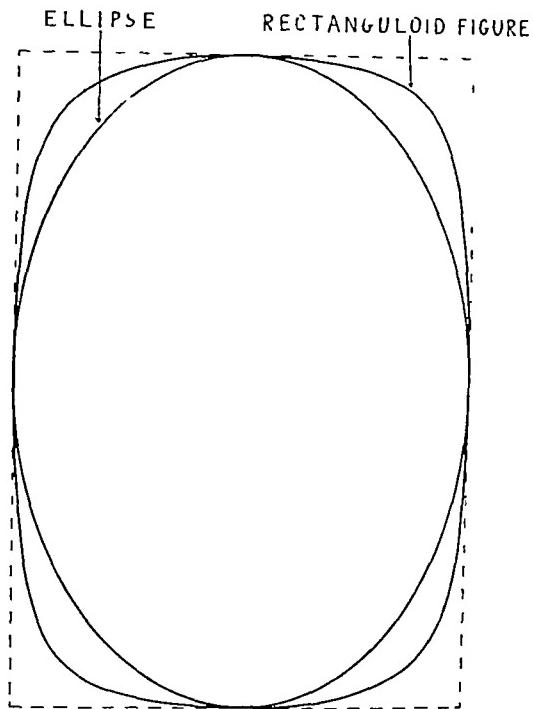

Diagram II Elliptical and rectanguloid focal spot shapes in a circumscribed rectangle.

ure These characters are also shown in Diagram VI

Since the focus of a tube is so widely variable, it is necessary to deduce a practical or *effective* focus that may be used as an index to radiability over a film as a whole In a former publication³ it has been shown that the average of the longest and shortest diameters (major and minor axes) of the projection figure at the middle of the cathode end of a film (Pos C, Diagram I) offers a fair "effective value" of the focus This value will, of course, vary with the size of the film with the target-film distance, and with the geometric characters (slope, shape, etc.) of the focal spot

(Although the mean of the major and

be shortened and the area therefore decreased, to project as in the lower row, the major axis would be lengthened and the area increased. Unless the focal spot is parallel to the film, it is apparent that a circle may be projected at only one point at a time. In determining the type of elliptical projections that is most desirable, it is, in the first place, fundamental that the most efficient possible geometric shape of projection figure is the circle. That is, a focal spot of given area will produce the greatest possible average sharpness at a point on a film, if the shape of the focal spot is such as to give a circular projection figure at that point. There remains to determine at what point on a film the circular focus should be projected for the greatest benefit to the film as a whole. The figures in the diagram are the area of focal spot which projects unit focus at the point depicted. The data refer to a 17-inch film length at 24 inches target-film distance.

It will be observed from the diagram that efficiency at the cathode end of the film is greatest when the circular focus is projected at that point. Since this projection has been shown to be the most reliable index to radiability over the film as a whole,³ it would seem desirable to design the focal spot to give the greatest possible efficiency at this location. There are, however, certain objections to this type of projection:

1. The gain is localized, and is obtained at the expense of efficiency over the film as a whole (see center and anode positions, and mean efficiency).
2. Symmetric distortion of shadow is obtained only where the focal spot projection is circular, hence the inevitable distortion of shape of shadow will be at a minimum when the circular focus is projected at the center of the film.
3. As film size is increased or target-film distance lessened with a given tube, the resulting changes in projection are least unfavorable when the circular focus is projected at the center of the film.

In view of the above data, and since the

gain is less than 2 per cent under the most extreme conditions, we are of the opinion that this fractional improvement is not

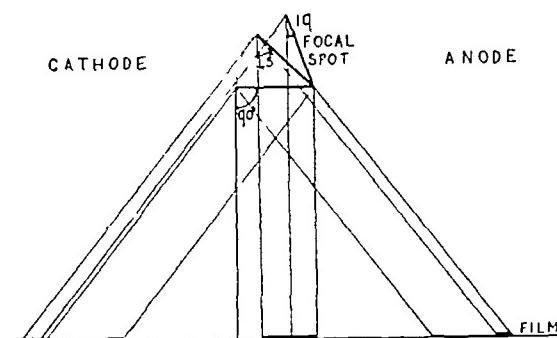

Diagram V Effect of slope of anode on film projection

earned and that the circular focus should be projected at the center of the film.

Projection of the circular focus at the anode end of the film results in very poor efficiency at the more important cathode end of the film and should not be employed.

The increasing efficiency from the cathode to the anode end of the film is simply an expression of the commonly observed increase in sharpness in this direction.

The Slope of the Focal Spot Surface—The effect on film projection of the angle of slope of the focal spot is shown in Diagram V. As the focal spot surface is rotated towards the perpendicular (perpendicular to the film), it is seen that the projections at the center and at the anode end of the film become rapidly smaller. It is apparent also that the anode end of the film may be placed behind the anode surface of the tube, and no radiation be obtained over this area. From the diagram it is seen that projection conditions throughout the film improve as the slope of the anode approaches the perpendicular. This may be conversely stated, that, for a given film projection, the length (and therefore area and capacity) of the focal spot increases as the anode surface approaches the perpendicular. This is the principle of the line focus tube.

film The conditions are for a 45° slope of anode at 24 inches target-film distance, centered over the 17-inch length of a 14×17 inch film It will be seen that the

jects unit focus remains larger in the case of the ellipse

Although we have been unable to obtain a purely mathematical proof for the general

Diagram IV Efficiency of types of focal spot projection

area of the elliptic focal spot is larger than that of the rectanguloid focal spot for all points of the film, i.e., the capacity and efficiency of the elliptical focal spot are greater. It is also seen that the difference in efficiency is most pronounced at the corners of the film. This is due to the fact that the projection figures' slope outwards at all points other than along the mid-axis of the film. The projection figures from a rectanguloid focal spot under these conditions suffer asymmetrical distortion as shown in Diagram III. The result is an increase in the size of the "effective focus" at a greater rate than that which takes place in the case of elliptical projections.

In contrast to this, the projection figures cast by an elliptical focal spot remain true ellipses under all conditions of slope and thus retain their symmetry over all parts of the film.

Similarly, for projection figures having a smaller area than that of an ellipse of the same major and minor axes, we have shown that the area of the focal spot which pro-

case, we deduce from these data that the ellipse is the most efficient possible geometric shape of focal spot design.

A further disadvantage of the rectanguloid focal spot is that the shadow cast by a small spherical object is given flattened sides, corresponding to the flattened sides of the focal spot, i.e., there is increased and asymmetrical distortion of shadow.

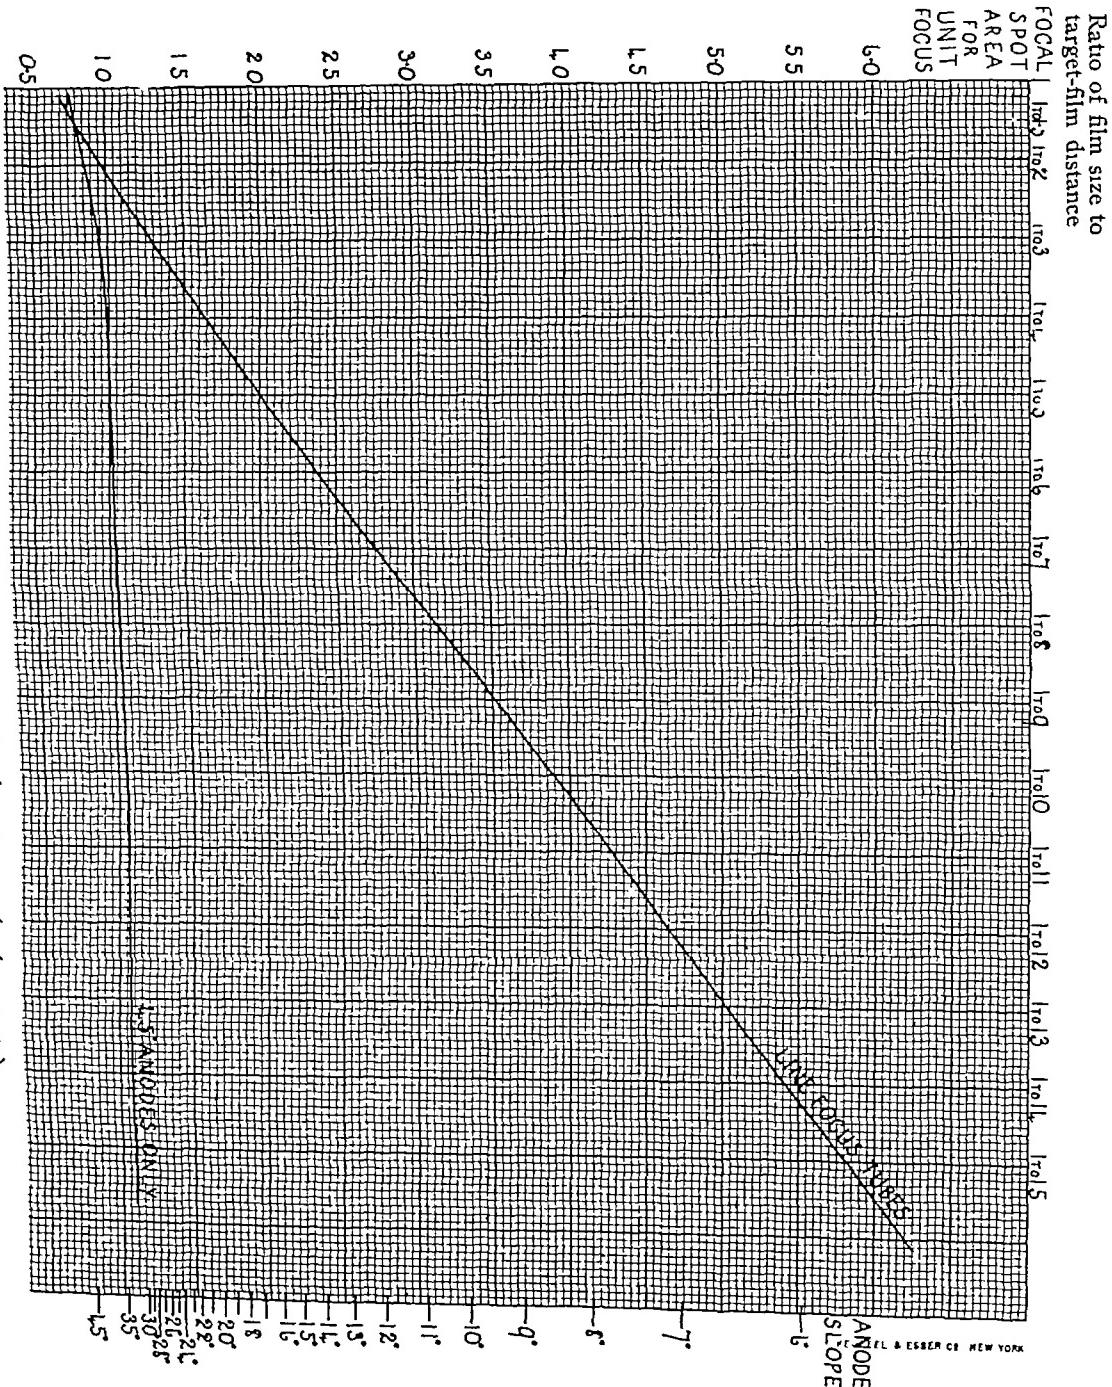

THE RELATIVE DIMENSIONS OF THE FOCAL SPOT

The relative dimensions of the focal spot, i.e., the ratio of the major to the minor axis, is determined for a given slope of the anode by the relative dimensions of the projection figures it is desired to cast upon the film. Diagram IV illustrates different types of elliptical film projections. The middle row illustrates the type of projection figures of the usual 45° anode tubes, i.e., a circle is projected at the center of the film. To project the type of ellipses shown in the top row, the major axis of the focal spot would

film should not be exceeded, and that a lower ratio is preferable when possible.

Relation of Slope of Anode to Focal Spot Area and Capacity—Graph I shows the efficiency of any slope of anode over any size of film at any target-film distance, subject to the conditions that (1) the focal spot is

elliptical, (2) the circular focus is projected along the central ray of the tube, and (3) that a two-to-one ratio between the maximum projection at the cathode end of the film and the minimum projection at the anode end of the film is not exceeded. The efficiency factor as before is simply the area

Graph I Relation of anode slope to focal spot area (and capacity)

This slope is, however, limited by two factors, first, the necessity for radiating the entire film (specifically the anode end), and, secondly, the difference between the maxi-

ferent parts of the film by an elliptical focal spot. In each case at the center of the film the shadow is circular, and the penumbral shadow is of uniform width in all directions.

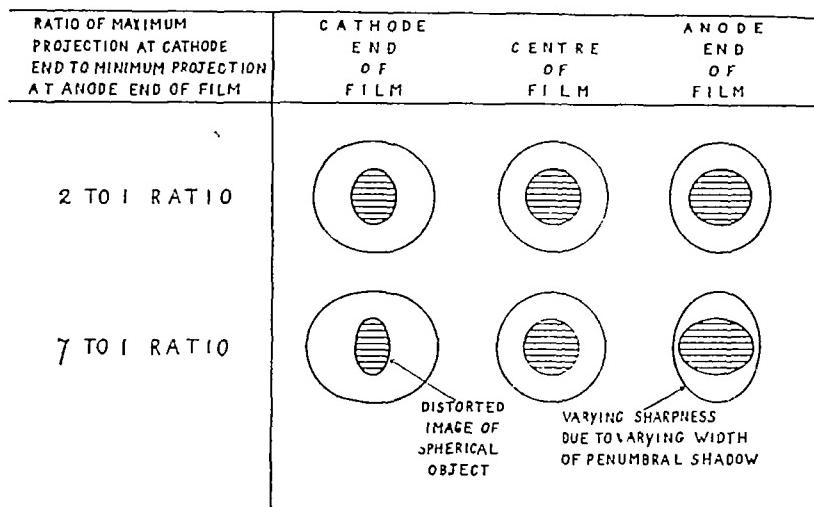

Diagram VI Images of a spherical object at different parts of a film

mum and minimum projection over the film (distortion) that we are willing to allow. Both of these factors are dependent, in addition to the slope of the anode, upon the ratio of the film size to target-film distance in use.

In determining the ideal degree of anode slope, it must be realized that we cannot design a single tube to function with equal efficiency under different conditions. The greater the tube distance and the smaller the film size we are willing to use, the greater the *relative* efficiency that can be designed into the tube.

Focal Spot Projection Ratios—We have first then to set a limit to the ratio of the maximum to the minimum projection that we are willing to permit over a film. This determines the degree of difference in sharpness between the two ends of the film and the degree of distortion of shape of shadow. The radiographic effect of different ratios of projection is shown in Diagram VI. These are the shadows that would be cast by spherical objects over dif-

At this point then the sharpness is uniform in all directions and distortion of the size and shape of the shadow is symmetrical, i.e., the shadow of a sphere is projected as a circle. At the cathode end of the film, however, the shadow proper is flattened and at the anode end of the film it is elongated. In addition, the width of the penumbral shadow (sharpness) varies markedly in different directions in these two positions. The figure shows the radiographic effects of a two-to-one and of a seven-to-one ratio between the projections at the anode and cathode ends of the film. The distortions increase with the ratio of maximum to minimum projection in effect, and we must decide what ratio we are to allow in designing the focal spots.

From the study of a series of such preparations using inanimate objects and living tissues, we have concluded that a ratio of two to one between the maximum projection at the cathode end of the film and the minimum projection at the anode end of the

energy was otherwise not available. However it is preferable to use the film dimension as the basis of computation except when limited by resources of energy or by tube capacity.

Similarly an 18° slope of anode could be used for chest exposures at 65 inches, and have a capacity of 85 per cent greater than that of a 45° anode giving the same sharpness at the same distance.

If in the future we are willing and able to use still greater tube distances, it is seen from the foregoing that much greater relative capacity can be designed into tubes for chest work by using still smaller slopes of anode.

Consider the use of the line focus type of tube in radiography of other parts of the body. Graph II shows, for example, the dimension of film that may be covered by an 18° anode at the shorter target-film distances. Since the conventional X-ray table assembly sets a practical limit in the neighborhood of 36 inches to the target-film distance that may be employed, let us see what radiographic procedures may be legitimately conducted using such a structure.

The graph shows that the limit of film dimension under these conditions is set at eight inches for a 37-inch target-film distance for this particular slope of anode. This permits the use of an 8×10 inch or an 8×12 inch film. These sizes, or smaller, are adequate for exposure of the extremities, including the hip joints and shoulder joints, for the cranium, and for sections of the spine. Radiographs of longer sections of the spine are unsatisfactory in any event, as quite different exposures are required in different regions. Smaller film sizes may be used at shorter target-film distances as shown by the graph. For instance, the 5×8 inch half of an 8×10 inch film may be used for radiographs of the sinuses at 24-inch target-film distance, the long axis of the tube being placed along the 5-inch dimension of the film.

But how, then, is radiography to be conducted when larger film dimensions are needed? In the first place, if it is necessary to expose a 14- or a 17-inch film length at 25-inch target-film distance, it is seen from Graph I that only a 45° anode may be used. In the case of an 18° anode, it is seen from Graph II that for a 10-inch film length (10×12 inch film) a target-film distance of 46.5 inches is indicated, and, for a 12-inch length, a target-film distance of 56 inches is required, *i.e.*, approaching four and five feet, respectively. The choice lies between using these unusually long target-film distances, or using an anode of lesser slope. When possible, the preference should invariably be for the former.

The trend of development in X-ray equipment is distinctly towards the use of generators of large capacity and tubes of increased capacity. The increased capacity made available by the line focus principle should be used to improve sharpness and radiability in detailed structures, and, aside from the attaining of speed where movement is a factor (thorax), should be employed to attain increased target-film distance.

It is apparent that X-ray table equipment should provide for such increased target-film distances in order to keep pace with this trend of developments.

Failing the use of adequate target-film distances, one has the option of using a lesser slope of anode, with consequent lessening in capacity, or of using smaller film sizes, *i.e.*, radiographing more limited areas at a time.

The user of line focus type tubes would do well to construct for himself a graph line for each slope of anode he may have in use. To construct the line as in Graph II, for example, for an 18° anode, proceed as follows. In Graph I, follow the 18° position to the left to the graph line and from thence to the top of the page. This will indicate the ratio of film size to target-film distance to be 1 to

of focal spot which projects unit focus at the middle of the cathode end of the film, the target, of course, being centered

At the right-hand edge of the graph is given the degree of slope, and at the left-hand edge the corresponding area of the focal spot. The figures across the top give the ratio of the film size to the target-film distance. For example, a ratio of one to six represents a film size of four inches at 24 inches target-film distance, or a film size of 12 inches at 72 inches, etc.

The graph in the first place shows the minimum target-film distance at which any slope of anode may be placed without exceeding a two-to-one ratio between the maximum and minimum focal projections. For example, let the long axis of a tube with 20° slope of anode be centered over a 14-inch film length. Tracing the 20° position to the left until it meets the graph line, and then upwards, it is seen that a film-size to target-film distance ratio of approximately 1 to 4.2 may be used. Multiplying each side of this ratio by the film size, we find that a 14-inch film size calls for a minimum target-film distance of $14 \times 4.2 = 58.8$ inches for this slope of anode. If the 20° line is then followed across to the left-hand column, it is seen that 1.70 is the area of this focal spot which will produce unit focus. To compare the efficiency of this tube with that of a 45° slope of anode, reference should be made to the nearly horizontal graph line across the bottom of the page. For the same film size ratio (*i.e.*, 1 to 4.2), it will be found that the area of the focal spot of the 45° anode is 0.99 as compared with an area of 1.70 for the 20° anode. Thus the 20° anode tube has a capacity of $\frac{1.70}{0.99} = 1.72$, or 72 per cent greater than that of the 45° tube under the same conditions.

Similarly a 14° anode is shown to have a focal spot area of 2.38 as compared with 1.04 in the case of a 45° tube. The area

and capacity of the 14° focal spot is thus about 2.3 times greater than that of the 45° tube.

Following the 14° point on the graph line to the top of the page, however, it is seen that the necessary film size ratio is about 1 to 6.0. This means that the 14° anode, if used over a 14-inch film length, must be placed at a target-film distance of $14 \times 6.0 = 84$ inches, or 7 feet. The 45° tube, on the contrary, may be placed as close as 21 inches to a 14-inch film without exceeding the two-to-one projection ratio.

Glancing at the still smaller slopes of anode, capacities of four and five times that of the 45° tubes appear tempting. However, it will be seen that, to use these tubes, target-film distances of the order of 12 to 15 feet must be employed to cover a 14-inch film length as in chest radiography. Such distances are apt to exceed the capacity of commonly used equipment.

Practical Considerations.—The preceding example shows that a 14° slope of anode may be used over a 14-inch film length⁴ at seven feet target-film distance, and has a capacity 2.3 times greater than that of a 45° anode giving the same sharpness. Such a tube then should be useful in radiography of the chest. In determining the minimum target-film distance that may be employed, however, it should be pointed out that some latitude is afforded by reason of the fact that the part radiographed rarely covers the entire film. Thus chests exposed at six feet or more rarely occupy more than 12 inches of the 14-inch film length. If, then, for the case of the 14° anode we provide for a useful film size of 12 inches instead of 14 inches as above, the necessary target-film distance is reduced to $6 \times 12 = 72$ inches or six feet. This reduction might make possible exposures for which sufficient

⁴It is shown in a previous publication³ that the long axis of the tube should always be placed along the short axis of the film and that for stereoscopy the tube should always be tripped in its own lateral axis, *i.e.* along the longer axis of the film.

realized, *i.e.*, the sharpness that may be attained for a given amount of energy is not obtained

5 The anode end of the film may suffer from lack of radiation

SUMMARY

1 The design of the focal spot of the X-ray tube is analyzed in terms of the area of the focal spot in relation to sharpness of focus

2 It is shown that the efficiency of the "line focus" type of focal spot may be substantially greater than that of the 45° slope of anode

3 It is shown that the "line focus" type of focal spot has limitations as to the film distance at which it may be employed. These distances are tabulated for practical use, and it is shown that failure to observe these limitations may lower the efficiency below that of the 45° anode

X-rays Detect Lead Poisoning in Children
—A new method of diagnosing lead poisoning by means of X-rays has been reported by Dr Edward C Vogt, of the Infants' Hospital and the Children's Hospital, Boston. When lead is absorbed into the body it is stored in the bones and can be detected in the X-ray films as a dense band at the growing margin. Its elimination following treatment can also be observed by means of X-ray films

Dr Vogt pointed out that lead poisoning is a frequent and serious condition in children

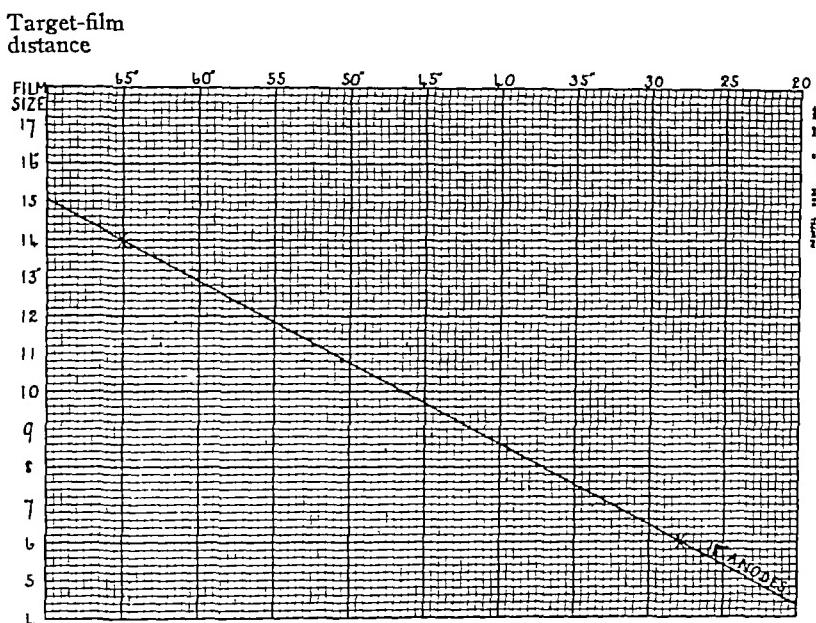

and one not always easy to diagnose. The dark line, called the "lead line," at the margins of the gums is significant of the disease in adults but is seldom seen in small children, and the other diagnostic tests require considerable technical skill

The X-ray test for lead poisoning cannot be used alone, Dr Vogt pointed out, as some other conditions give the same or nearly the same picture, but together with other evidence, such as a history of chewing painted toys, it is very useful.—*Science Service*

465 The target-film distance is thus 465 times the film length. A 6-inch film then calls for $6 \times 465 = 279$ inches target-film distance, and a 14-inch film requires $14 \times 465 = 651$ inches target-film distance. It

measure the angle between this line and a perpendicular to the line representing the axis of the tube

In the case of tubes with metallic discharge chambers, the user will have to de-

Graph II

is necessary only to plot these two positions by crosses and join their centers with a straight edge. Any number of tubes may be thus represented upon a single sheet of co-ordinate paper.

The Determination of the Slope of the Anode—In order to use the material in this paper, it is of course necessary to determine the slope of the anode. The manufacturer should supply these data with each tube as well as the dimensions of the central ray projection of the focal spot. We presume this will be supplied on request. The slope of the anode may be approximately measured in the case of tubes with glass bulbs. Support the tube over a sheet of white paper on which is a long, straight ink mark, and line up the central axis of the tube with this mark by eye. Place a straight edge to coincide in direction with the face of the anode and mark the edge. With a protractor

pend on the manufacturer for these data. Projection methods of measuring the slope of such anodes will be published at a later date, but are not suited to use by the practical radiologist. Failure to observe the restrictions as to target-film distance laid down in this paper may invoke penalties as enumerated below.

1 Undue distortion of shape of shadow, i.e., identical objects may give unduly different radiographic characters of shadow at different parts of the film.

2 There may be undue variation in the degree of sharpness over different parts of the film.

3 Actual sharpness is apt to be defective, as the size of the focal spot is in general adjusted by the manufacturers to be suitable for use at the distances which the slope of the anode permits.

4 The full efficiency of the tube is not

thetic ganglion, brought about no apparent changes in the gland or in its thyroglobulin content. Extirpation of the inferior cervical sympathetic ganglion, however, was followed by diminution in the size of the gland on the side of the operation and a decrease in its thyroglobulin content. He, therefore, concluded that the sympathetic innervation of the thyroid exerts both trophic and secretory influences.

Asher and Flack (1) assumed the existence of secretory nerves to the thyroid gland mainly by reason of the fact that stimulation of the laryngeal nerves brings about the same heightened excitability of the depressor nerve and increased effect of adrenalin on blood pressure as is brought about by the intravenous injection of thyroid preparations. Asher and Rodt (3) also observed that the excitability of the splanchnic nerves is heightened during stimulation of the nerves to the thyroid gland.

In a further experimental investigation, carried out under Asher's direction, Ossokin (11) corroborated the findings of the earlier investigators who maintained that the nerves to the thyroid gland convey both vasoconstrictor and vasodilator fibers. He also reported that vagus excitability is increased during stimulation of the nerves to the thyroid gland. More recently Asher and Pfluger (2) reported experimental findings which seem to indicate that sympathetic denervation of the thyroid results in diminution of the capacity of the body tissues, particularly the subcutaneous connective tissue and muscles for absorption. They concluded, on the basis of these findings, that at least some of the normal functions of the thyroid gland depend on its sympathetic innervation.

In perfusion experiments on the thyroid of the dog, with the nerve supply intact, only by the use of adrenalin could Sturm (13) elicit the discharge of iodine-con-

taining material into the perfusion fluid. According to Vogt (14), partial sympathetic denervation of the thyroid gland in rats and its complete sympathetic denervation in rabbits failed to influence the capacity of the thyroid to adjust itself to wide variations in the intake of food.

The experimental data at hand seem to demonstrate the existence of both vasomotor and secretory nerve fibers to the thyroid gland. The effect of secretory fibers is less evident, however, in the activity of the thyroid gland than in that of certain others, e.g., the salivary glands. Vasomotor changes in the thyroid probably play an important rôle in its secretory activity. The possible effect of direct secretory fibers, however, cannot be disregarded, but the data available at present do not afford a basis for the evaluation of the rôle of these fibers either in the functional regulation of the thyroid under normal conditions or under conditions of hypo- and hyperthyroidism.

On the basis of clinical observations, it must be conceded that hyperactivity of the thyroid gland is accompanied by nervous hyperirritability. The specific effect of the thyroid secretion on the nervous system, however, is not fully known. The data available seem to indicate that the thyroid secretion affects mainly the sympathetic division of the autonomic system, but, under certain conditions, it also affects the parasympathetic nerves. Many of the experimental data bearing on this point are inconclusive. For example, Lieb and Hyman (7) have shown that repeated injections of adrenalin in experimental animals increasingly augment irritability of the sympathetic nerves, regardless of the functional condition of the thyroid gland. In a study of the effect of thyroidectomy on sympathetic irritability, Hoskins (5) was unable to obtain consistent results in the various experimental animals used, probably due to varying effects.

FUNCTIONAL INTERRELATIONSHIPS OF THE THYROID GLAND AND THE AUTONOMIC NERVOUS SYSTEM¹

By ALBERT KUNTZ, M.D., ST. LOUIS, MISSOURI

THE nerve supply of the thyroid gland is derived in part from the cervical sympathetic trunks and in part from the vagus nerves. In man, the sympathetic nerves to the thyroid gland arise mainly from the middle cervical ganglion or, in the absence of this ganglion, directly from the cervical sympathetic trunks. These nerves probably include fibers arising in all the cervical sympathetic ganglia. Nonidez (9) recently described a definite bundle of fibers arising in the superior cervical ganglion and entering the corresponding lobe of the thyroid gland of the dog. He expressed the opinion that the superior cervical sympathetic ganglia are the sources of most of the sympathetic fibers which enter the thyroid gland. Since the thyroid gland develops as a diverticulum from the floor of the embryonic pharynx, a portion of the digestive tube which receives its sympathetic nerve supply chiefly from the superior cervical ganglia, this opinion seems to be well founded. The fibers of vagus origin which enter the thyroid gland are mainly components of the superior laryngeal nerve and include both afferent and efferent fibers. The terminal relationships of the efferent vagus fibers could not be interpreted on the basis of the findings of the earlier investigators. Since the existence of ganglion cells both in the superior laryngeal nerve (6) and the thyroid gland (9) has been demonstrated in certain animals, particularly the dog, it may be assumed that efferent components of the vagus terminate in relation to these cells. They are multipolar and probably represent parasympathetic neurons.

In the light of these findings, it may be

assumed that the thyroid gland, like most of the other visceral organs, is supplied by both sympathetic and parasympathetic nerves. The thyroid gland is abundantly supplied with blood vessels. Not a few investigators have failed to observe nerve fiber terminations in relation to the thyroid follicles or gland cells, and, consequently, have assumed that the nerve fibers which enter the thyroid gland are distributed mainly to the blood vessels. The majority of the more recent investigators who have studied the distribution of nerve fibers in the thyroid gland support the theory that the fibers terminate both in relation to the thyroid follicles and in the walls of the blood vessels.

Certain of the older physiologists, particularly Poincare (1875), advanced the theory that the thyroid gland is supplied by secretory nerves, although experimental data were not at hand. Of the later investigators, some have advanced experimental data which seem to indicate that thyroid activity is subject to direct nervous influences, others were unable, on the basis of their experimental findings, to concur in this opinion. Of the latter group, not a few supported the theory that the secretory activity of the thyroid gland is influenced by the blood supply to the gland, consequently, thyroid activity is influenced indirectly by the vasoconstrictor and vasodilator nerves.

In an investigation undertaken to determine the possible direct nervous influence on the secretory activity of the thyroid gland, Wiener (15) cut the various nerves to the thyroid on one side and later compared the lateral halves of the gland with respect to weight and thyroglobulin content. In his experiments section of the vagus or extirpation of the superior cervical sympa-

¹Read before the Radiological Society of North America at the Seventeenth Annual Meeting at St. Louis Nov. 30-Dec. 4 1931

ganglion cells also occur in association with other diseases, including acute and chronic infectious diseases. In infectious diseases such changes must be regarded not as a cause but as a result of the disease. To what extent changes in the sympathetic ganglion cells, indicating hyperstimulation, play a rôle in the genesis of hyperthyroidism is unknown. That sympathetic hyperirritability plays an important rôle in the course, termination, and sequelæ of the disease cannot be doubted.

Although in some cases pre-existing functional disturbance and pathologic lesions of the autonomic nervous system must be regarded as etiologic factors in hyperthyroidism, in the majority this condition probably arises as a primary disease of the thyroid gland. Since certain of its dominant symptoms, including tachycardia, exophthalmos, perspiration, and diminished gastric secretion, are directly referable to increased sympathetic stimulation, probably due to the increased output of the thyroid hormone, it must be admitted that the autonomic nervous system plays an important rôle in the symptom complex associated with hyperthyroidism. This factor merits greater consideration in the treatment of the disease than is usually accorded it, since the sympathetic hyperirritability resulting from this disease, or associated with it, in turn affects the thyroid gland unfavorably. Measures which tend to restore the functional balance of the autonomic nervous system, therefore, would also tend to remove one of the chief sources of irritation of the thyroid gland.

of this procedure on the sympathetic and parasympathetic divisions of the autonomic system

The results of experimental studies reported recently by Bergwald and Kuschinsky (4) are more significant. These investigators have shown that thyrotoxicosis, induced by the administration of thyroxin, results in sympathetic hyperirritability by reason of an increased output of adrenalin, *i.e.*, thyroxin poisoning results in increased secretory activity of the adrenal glands. These results strongly suggest that sympathetic hyperirritability in cases of hyperthyroidism may arise as an indirect result of the stimulating effect of the increased output of the thyroid secretion on the adrenal glands. These investigators also showed that the direct action of thyroxin is essentially peripheral. Certain observations of Oberdisse (10) also indicate that thyroxin in the blood stream may exert a direct effect on the tissue elements.

Although the results of experimental investigations show clearly that the thyroid gland is subject to nervous influences under experimental conditions and that the thyroid secretion acts as a sympathetic stimulant, the functional interrelationship of the thyroid gland and the autonomic nervous system, as suggested by the experimental data, is not clear-cut. Whatever influence the thyroid secretion exerts on the nervous system probably is exerted mainly on the sympathetic nerves. Under certain conditions, however, it also influences the parasympathetic nerves. This non-specific action of the thyroid secretion cannot be explained on the basis of any experimental data available at present.

In view of the fact that the results of experimental investigations fail to show a constant and clear-cut functional interrelationship of the autonomic nervous system and the thyroid gland, it is hardly to be expected that the clinical picture in thyroid disease should be constant and clear-cut. The domi-

nant symptoms of hyperthyroidism, *viz.*, tachycardia, exophthalmos, increased metabolism, fever, etc., are manifestations of sympathetic stimulation. The hyperperistalsis, which so commonly is associated with hyperthyroidism, on the other hand, is a manifestation of parasympathetic stimulation. The functional balance of the autonomic nervous system is disturbed, but the symptom complex as a whole suggests neither clear-cut sympathetic tonus nor clear-cut vagotonia.

In the genesis of thyroid disease, the importance of a pre-existing functional imbalance of the autonomic nervous system is unknown. Data are not wanting, however, which support the theory that hyperthyroidism is of neurogenic origin in certain cases. Not infrequently the symptoms of hyperthyroidism may be recognized in the absence of any demonstrable lesion of the thyroid gland. In certain cases, it has also been possible to trace the cause of thyroid hyperactivity to a specific lesion of the cervical sympathetic. For example, Herzen reported a case of unilateral thyroid hyperactivity due to compression of the cervical sympathetic by a fractured clavicle. In this case, the symptoms of thyroid hyperactivity subsided following removal of the pressure by reduction of the fracture. Symptoms of hyperthyroidism brought about by stimulation of the thoracic sympathetic trunk also have been reported. According to Stammle (12), Mogilnizky (8), and others, hyperthyroidism frequently is accompanied by pathologic changes in the autonomic ganglia and ganglion cells. These changes have been studied mainly in the ganglia of the sympathetic trunks, and are such as would suggest hyperactivity of the sympathetic ganglion cells. There is also a degree of parallelism between the severity and duration of thyroid hyperactivity and the extent of the changes in the sympathetic ganglion cells. Similar changes in the autonomic

ganglion cells also occur in association with other diseases, including acute and chronic infectious diseases. In infectious diseases such changes must be regarded not as a cause but as a result of the disease. To what extent changes in the sympathetic ganglion cells, indicating hyperstimulation, play a rôle in the genesis of hyperthyroidism is unknown. That sympathetic hyperirritability plays an important rôle in the course, termination, and sequelæ of the disease cannot be doubted.

Although in some cases pre-existing functional disturbance and pathologic lesions of the autonomic nervous system must be regarded as etiologic factors in hyperthyroidism, in the majority this condition probably arises as a primary disease of the thyroid gland. Since certain of its dominant symptoms, including tachycardia, exophthalmos, perspiration, and diminished gastric secretion, are directly referable to increased sympathetic stimulation, probably due to the increased output of the thyroid hormone, it must be admitted that the autonomic nervous system plays an important rôle in the symptom complex associated with hyperthyroidism. This factor merits greater consideration in the treatment of the disease than is usually accorded it, since the sympathetic hyperirritability resulting from this disease, or associated with it, in turn affects the thyroid gland unfavorably. Measures which tend to restore the functional balance of the autonomic nervous system, therefore, would also tend to remove one of the chief sources of irritation of the thyroid gland.

THE SURGICAL ASPECT OF THYROTOXICOSIS¹

By WILLARD BARTLETT, M.D., F.A.C.S., and WILLARD BARTLETT, JR., M.D.,
St. Louis, Missouri

ASOLUTION of the matter under discussion is simplified, we think, by asking ourselves four questions (1) How does the problem in general impress a surgeon who has studied it for many years in a large number of patients? (2) What sort of individuals are these who are subject to this ailment? (3) What manner of clinical course is characteristic of it? (4) What therapeutic measures seem logical to one who has spent a large part of his professional life in trying to answer the first three of these four questions?

We realize that we are not addressing men who represent a cross-section of the medical world, but that our remarks are directed toward highly trained specialists who do not now practise, and many of whom never have practised, general clinical medicine. Hence possibly we do not see eye to eye, however desirous we may all be of keeping the open mind in every discussion of this sort. What follows has, therefore, no personal slant, since the men to whom this is presented probably see all of these patients in the capacity of consultant, whereas the real odium which attaches to therapeutic failure is in most instances to be borne either by the physician who first sees the patient or, indeed, in this malady of them all, by the patient herself.

Toxic goiter will, we think, impress us with its grave potentialities only when we consider that it gravely affects the three vital systems without any one of which life is not possible for more than a minute or two. We refer, of course, to the central nervous system, the circulatory system and the respiratory system. Thyrotoxicosis in its gravest form is surely recognized by circu-

latory manifestations which are well known to you all, by nervous manifestations which are easily apparent to a casual observer, and by respiratory alterations which present themselves to all students of basal metabolism and to those conversant with our own work on the duration of voluntary apnea.

With this background of physiology in mind, let us ask ourselves if the malady is satisfactorily treated to-day. We were hardly able to answer this question until we made mortality studies on all the goiter patients who died in our service during the past six years. To our astonishment, and we may add to our melancholy satisfaction, we found that 38 per cent of these deaths occurred before operation, something which seems almost incredible in view of the promise held out to us a few years ago—that Lugol's solution would prevent what were termed “medical deaths” in thyrotoxicosis. Now, to make our position more clear as to who is blameworthy, we will add that 80 per cent of those who died without an operation had had a goiter from 8 to 30 years and, what seems even less credible, that 65 per cent of them had been toxic for more than one year.

These surely are figures which give all of us, physicians as well as patients, pause for thought. How is such a condition of affairs possible in an enlightened age, with the laity rather acutely aware of most of its own needs and the medical profession surely well trained? Mature thought along these lines has convinced us that there are two factors which stand out above all others in explaining this situation. In the first place the thyroid patient is, as a rule, highly stimulated, and fails to sense her own need, or to regard herself as a sick person. In the second place, the physician at large is a highly com-

¹Read before the Radiological Society of North America at the Seventeenth Annual Meeting St. Louis, Nov. 30-Dec. 4, 1931.

placent individual when it comes to a study of this subject. One cannot otherwise envisage the policy of inaction or procrastination on the part of both patient and physician which leads to a situation such as that outlined above. If our figures mean anything, surely the patient and the doctor are playing with fire.

A further perusal of our records would indicate that the general practitioner does not recognize in toxic goiter any greater potential menace to the patient's health and life than he concedes to the general run of what he conceives to be surgical affections, among which appear many cases of hernia, varicose veins, hemorrhoids, ingrown toe nails, etc. We come to this conclusion because, for the past year, 42 per cent of our general surgery, exclusive of goiters, has been referred by practising physicians, whereas only 40 per cent of our goiters—with all their possibilities for disability and death—have been sent to us by physicians for treatment. This is almost incomprehensible to one who has seen 38 per cent of all the thyroid patients he has lost in six years die before they could be sufficiently rehabilitated for a surgical operation.

Let us continue with the results of our mortality studies as they were impressed upon us by the remaining 62 per cent, those who died following operation. Definite symptoms of toxicity had been present for over one year in this group. Of the patients dying after operation, death occurred in crisis, in afebrile circulatory failure, and from complications in about equal numbers. All of those dying in thyrotoxic crisis had been toxic for over 10 months, with one exception and were, with one exception, under 50 years of age. Those dying in afebrile circulatory failure were, with one exception, over 50 and had had their goiters for periods ranging from 10 to 26 years, only one, however, had had toxic symptoms for more than six months. The circulatory

systems of persons past middle life obviously stand poorly the added imposition of thyrotoxicosis. Again we are compelled, by a study of the patients who died following operation, as well as of those dying without it, to the conclusion that we were forced to receive these patients into a surgical service at a period of their illness when surgical treatment was attended by an unduly grave risk, one which we are hardly called upon to accept when confronted by the general run of patients.

The second question which we have undertaken to answer is, What sort of individual is the subject of thyrotoxicosis? If this is to be answered satisfactorily we must, we believe, look at the ailment as a phase of an existence into which it logically fits itself, in other words, the patient who presents herself with this malady was born possessing a potentiality which does not exist for the rest of us. If we may for a moment digress, the same line of reasoning must obtain for the rest of her life if a recurrence of the malady is to be prevented after we have succeeded in restoring her to health. The prime factors which would, in the light of our own experience, seem to merit consideration as causal factors are (1) instability of the patient, (2) undue physical or mental stresses, and (3) presence of a pre-existing simple goiter.

The first of these three influences was brought out in no uncertain manner among the troops overseas in the late war. A certain degree of instability was easily overlooked. The young man went overseas where the stress, both emotional and physical, was beyond anything that troops had previously endured, with the result that thyrotoxicosis developed in a wholly unexpected percentage of cases. We believe our own figures, quoted above, are fairly representative of the fact that very many patients have been aware of a thyroid tumor long before the appearance of toxic symptoms.

The third question to be answered must regard the character of this malady. We must surely have a true understanding of its life history if we expect to combat it successfully. It must be fully understood that its course is marked by *remissions* which are to be regarded as *automatic* in character, though, of course, they may be influenced—and, indeed, precipitated—by certain forms of treatment to be detailed later. These remissions usually persist for some months after the patient has experienced an incapacity of a somewhat similar duration. It may be added, one regrets to admit, that a complete *restoration* to health, which is spontaneous in character—that is, a symptomatic cure—is exceedingly rare. In a wide experience extending over many years, we are absolutely certain of this having occurred in only one patient. Perhaps we may except those occasional "burned-out" sufferers who have managed somehow to exist through some ten (average) exacerbations, only to attain at last a permanent subthyroid state, accompanied by irreparable damage to the heart and parenchymatous organs. If *restoration* is to be brought about at all, it must be *constructive* in character as opposed to the remission which we have termed *automatic*, upon this consideration will be based our suggestions for treatment.

(One phase of the subject should not be passed over lightly, but the limits of this paper do not permit us to go deeply into it namely, the diagnosis. There is a very considerable percentage of patients in whom it is most difficult to know whether we are dealing with thyrotoxicosis or some one of the many emotional or psychic conditions characterized by vascular and emotional instability and other phenomena which also characterize the thyrotoxic patient. We hoped at one time that the basal metabolism determination would help us out in this connection, but we will remind you once more that, during the remission the basal metab-

olism may be quite within normal limits and this fact has led to confusion in diagnosis. However, these two classes of patients must be sharply separated unless disappointment and something like disgrace are to follow the removal of an enlarged thyroid for symptoms which have not been of thyrotoxic origin.)

The individual and not the disease is to be studied. With this in mind we are presenting quite briefly the nine criteria by which, in our own service at least, an attempt is made to estimate the severity of thyrotoxicosis and to formulate therapeutic indications in each patient who presents herself

1 *Heredity*.—We can dismiss this matter with a mere statement that the ancestors of every individual determine to some extent the quality of tissue he brings into this world and the indefinite something which we will call (for want of a better term) his life expectancy.

2 *Age*.—Much observation in many hands has shown that the thyroid patient under 18 and the one over 50 years of age carry distinct handicaps with them. A surgeon feels that he cannot take away a relatively large percentage of thyroid tissue in childhood or early youth without interfering with growth, development, etc. On the other hand, he risks a high percentage of recurrence in these young patients by leaving too much thyroid tissue. The patient over 50 presents quite another sort of consideration, for she has not the physical reserve to meet any emergency in the same way she would have done on the sunny side of the half century mark.

3 *Duration*.—The long-continued existence in the toxic state tends, in the course of time to bring about parenchymatous changes in all the organs, though the long-continued presence of the thyroid tumor itself may have meant very little in a mechanical sense.

4 *Circulation*—The increased oxygen need, which characterizes thyrotoxicosis, is met in part by cardiac over-activity which leads, in the course of time, to something akin to the state that is suggested by the overworked race horse which has been pushed unmercifully in the last quarter until the point of exhaustion has been reached.

5 *Excretion*—In this connection we refer in passing only to sweating, diarrhea, vomiting, bronchorrhea, and the changes in kidney function which are seen in the advanced stages of the disease. We realize, of course, that it is difficult to separate the rôles played by secretion and excretion in a study of this phase of the malady.

6 *Nutrition*—No better evidence of thyrotoxicosis can be elicited than a history of rapid loss of weight, especially if accompanied by a ravenous appetite, provided, of course, that diabetes be excluded. However, this cannot always be done because the two maladies run concurrently more often than is supposed to be the case. It must be understood that nutritional decline is always to be regarded as involving one of the worst prognostic indications.

7 *Self-control*—A partial or complete loss of self-control is to be regarded as very serious in every instance, and, when a true psychosis has developed in such a patient, the likelihood of a fatal outcome is much increased. This is especially true if anything of a surgical nature is undertaken.

8 *Metabolism*—This index of the severity of the disease is too well known, we think, to justify us in any extended consideration of it, but it varies widely in each individual at different stages of the disease.

9 *Duration of Voluntary Apnea*—In recent years it has seemed to us that study of a patient's ability to hold her breath has given a criterion which teaches us more about the patient's vital reserve than does any other single one at our command. Indeed, it reflects something of that which is

imparted by a study of three other criteria, namely, circulation, self-control, and basal metabolism. A preliminary report along these lines was presented by one of us, the junior author, to the American Society for the Study of Goiter at the Seattle meeting in July, 1930. The pearl-diver can hold his breath an unbelievably long time, Jackson and Lees, who examined 100 healthy students, found the duration of voluntary apnea to be 72 seconds after inspiration and 34 seconds after expiration, we find occasional strong men in whom it is 100 after inspiration and 50 after expiration. Contrast this with the lowest figures we have observed in a goiter patient who could hold her breath only five seconds after inspiration and an equal length of time after expiration. As a graphic portrayal of just what this means in thyroid surgery, we will say that in July, August, and September of this year we felt justified in doing thyroidectomy on the patients who entered the hospital with an average DVA of 47/24, but nothing more than ligations on those who came in with an average DVA of only 22/13.

The fourth question which we are asking ourselves is, What shall be done by our profession about the goiter problem? As we see it, experience forces upon us the following concept of the whole goiter matter. There must be, first, a considerable period, if the individual is very sick, for *rehabilitation*, the average duration of this period being about one year. This is succeeded by what may, for want of a better term, be called a *maintenance* period, which lasts as long as the patient lives and is devoted to maintaining an adequate level of health and prevention of recurrence. The rehabilitation period, so-called, consists of three phases. We formerly called the first one "preparation for operation" and the third one "after-treatment, immediate and remote," these two being separated from

one another by the second phase, a surgical procedure calculated to decrease greatly the amount of thyroid tissue. We do not now think it fair to the patient to separate these three phases of rehabilitation. We rather consider it essential to inform her when she is first seen that the rehabilitation is going to take a year and that the three phases of it are of about equal importance.

There are five measures at our command which shorten the first phase of rehabilitation during which the extremely sick individual improves to that point at which safe removal of the thyroid tissue can be contemplated. They are the use of (1) rest, (2) iodine, (3) radiation, (4) the injection of various substances, and (5) superior pole ligations.

It is impossible to state the exact value of any one or all of these five measures, since thyrotoxicosis is characterized by cycles in which a marked improvement appears periodically whether or not the patient is treated. It is only since we learned to do our operating in these periods of spontaneous or induced remission that the surgical mortality has approached a figure which justifies a continuance of thyroidectomy.

Our operative attack upon the gland should never be considered an emergency measure, on the other hand, if it is so employed, tragedies are very certain to be frequent. We are displaying a patient, Mrs G., on whom we employed radiation in a way which may be novel to many. Hers was such a stubborn case that on Sept. 17, 1931, we cut flaps as for a thyroidectomy completely exposed the anterior surface of the thyroid gland, and, with the wound open gave her the following exposure: 5 5-inch spark gap, 3 ma, 1 mm aluminum filter, 22-inch distance 5 minutes. The layers covering the thyroid were completely restored and the wound healing was uneventful. We have not performed this on a second patient preferring to wait six months to be sure that no permanent harm

has been done to the parathyroids or other important structures in the field thus exposed. We were led to radiate the patient in the manner outlined because, after cutting flaps, her condition became such that a continuation of the operation seemed inadvisable. With the flaps opened, it was apparently possible to do more than is accomplished by radiation when the integrity of the skin has to be considered.

The third phase of rehabilitation, the after-treatment, terminates in many hands when the patient leaves the hospital. A very great deal is gained by continuing to observe and advise the patient until a year has elapsed from the time when she was first seen. In this way one avoids the many errors which are inevitable from a too early return to work or to the numberless other reactions which can mean harm for the patient who has nothing but her own inclinations and experience to guide her. The period of life maintenance is not one of strictly *medical* treatment, but should, rather, consist of occasional *supervision* on our part and of *co-operation* on the part of the patient. It is only by some such arrangement that recurrence is to be prevented in a certain small percentage of cases, variously stated by different authors as up to 6 per cent. We send our patients home with instructions to take a small amount of iodine, one to three drops of Lugol's solution each day, feeling that thyroid metabolism is rendered less arduous if we are justified in the assumption that a gland which finds its work easy is less likely than another to undergo a compensatory hypertrophy.

The observer who has traced many of these thyroid patients through the years following the operation has long since become convinced that their judgment about themselves is in many instances not to be trusted. These patients, more than any others seem prone to the forms of indiscretion and immoderation which incline them toward a recurrence of their symptoms. They seem

often not to need a physician so much as they do need a custodian. Surely a judicious mixture of medical and custodial care is needed if these individuals are to remain healthy and useful after their period of rehabilitation is at an end.

CONCLUSION

It seems to us that there should be a complete understanding between the radiologist and the surgeon as to the field of usefulness of each in the treatment of goiter if they are to be mutually helpful in the highest degree to the patient. As we see it, there is involved absolutely no conflict of their interests. Each is more definitely useful than the other during a certain period of the goiter patient's treatment. Neither of them cures her, indeed, the word "cure" has not been used in this paper, advisedly, because the basis of the malady which we are discussing is unknown. What we do is to treat a syndrome and all we hope to accomplish is a certain *stabilization* of these patients which may, and should, remain permanent.

The period of usefulness which we, as surgeons, are definitely relinquishing to you, the radiologists, is coincident with the first stage of rehabilitation, that is, while we are trying to reduce thyrotoxicosis to the point at which surgery becomes safe. Radiation, during the period which we formerly called "preparation of the patient," is certainly not dangerous, and is surely efficacious at a time when the operative removal of thyroid tissue is absolutely dangerous. On the other hand, we would reserve for the surgeon the period which begins with the remission of symptoms. In other words, the thyrotoxic patient has passed through what may be broadly termed her crisis or at least her critical period, and has, with the aid of radiation, returned as nearly to the normal as may be possible with her gland in place.

Then, and not until then, the removal of about nine-tenths or even more of her thyroid tissue transforms this temporary remission into a permanent restoration to her normal status, provided, of course, that the proper sort of follow-up is contemplated. This selective procedure may, we think, be termed one of a quantitative nature since the removal of half the thyroid (one lobe) does not accomplish at all the same thing. (Nothing would be more desirable from the patient's point of view than the development of radiologic or other treatment which would remove or destroy nine-tenths or more of the thyroid gland without at the same time imperiling parathyroids and other important structures, to say nothing of producing complete hypothyroidism.) However, it would seem that mechanical removal, complicated as this procedure may seem when compared with radiation, must for the time being give the only promise of removing just the large proportion of thyroid tissue which is undesirable, and of leaving behind at the same time just the vastly lesser proportion which is indispensable to the continuance of the patient's health.)

From the foregoing it will appear that we do not consider either thyroidectomy or radiation the absolutely *vital* procedure in our treatment of thyrotoxicosis. Both are important within their own fields of usefulness. In the broadest sense, however, this is from first to last rather a problem of clinical management during a period which begins with the introduction of the patient to us and ends only when her measure of usefulness or, indeed, of existence is over. Does any radiologist wish to assume the sort of responsibility here involved? We think not. We hope not, at least, because we consider the radiologist far too useful a member of the medical profession in another capacity to permit him to employ his time in extended clinical pursuits.

THE SURGICAL TREATMENT OF THYROTOXICOSIS¹

By H. M. RICHTER, M.D., CHICAGO, ILLINOIS

HERE can be but one purpose in discussing the surgical treatment of thyrotoxicosis before this Society—that of giving a basis for comparison with the radiologic treatment. In this way only is it possible to estimate the relative value of the two procedures. To begin, therefore, there must be a definition of the terms used, otherwise, there is likely to be much misunderstanding.

I shall confine myself to the subject of thyrotoxicosis, which is a toxemia, and entirely disregard the term "goiter," referring to mere enlargement of the thyroid gland, which is not of concern in this discussion. Since we are interested in a comparison of the results obtained by these two methods of treatment for thyrotoxicosis, our evidence must show first, that the patients treated were really thyrotoxic, and, second, that the results of treatment are as stated and substantiated by adequate study.

A diagnosis of thyrotoxicosis can be made only after a personal study of the patient. It is evident that the status of the patient, when he first comes for treatment, can be determined only by means of personal, clinical, and laboratory examinations. In addition to the history and physical examination, laboratory tests give important diagnostic information. It seems equally evident that an estimate of the post-operative condition, that is, the results obtained by treatment, must depend equally upon skillful clinical and laboratory studies. Obviously, then, it is impossible to depend upon correspondence for furnishing the diagnostic information. Neither a report from the patient himself as to subjective symptoms, nor a report from the family physician con-

cerning objective findings can be used as a basis for critical study. It is not true that the patient is the best judge of his own condition. His estimate is likely to be faulty and misleading, depending to a great extent upon his emotional make-up. An outstanding symptom of thyrotoxicosis is increased nervous irritability, a symptom present in many other disorders, and one which is quite likely to interfere with subjective observations of any sort.

The personal contact between physician and patient is of the greatest importance in clinical medicine. It is only through securing a complete anamnesis and by making a careful physical examination that an accurate diagnosis is possible. In addition, students of thyroid disease are practically agreed that repeated studies of the basal metabolic rate form another objective basis for judgment of the patient's condition. It naturally follows, therefore, that those who discuss thyrotoxicosis must be able to vouch for the clinical evidence and for the accuracy of the metabolism studies made on the patient.

The case reports which form the basis for this presentation are those of patients who were given this type of careful study. The majority of the metabolism tests were made by skilled technicians in my own laboratory. The remainder were made in laboratories for which I, personally, can vouch. All cases in which this type of data was not available were excluded from this study. To eliminate a possible source of error, cases are not included in which pre-operative or post-operative metabolic or other data were obtained by correspondence with the patient or his physician. In comparing the results obtained by radiologic treatment of thyrotoxicosis with those ob-

¹Read before the Radiological Society of North America at the Seventeenth Annual Meeting at St. Louis Nov. 30-Dec. 4, 1931.

tained by surgery, it is necessary that you be equally as critical of your material Patients concerning whom the statement is made, "They came with a diagnosis of thyrotoxicosis," whose metabolism studies were uncontrolled, or those who had no such studies, cannot be included in any scientific study without danger of error Starting with these premises, we shall both be able to talk in exact figures We can eliminate entirely such terms as "approximately" or "about" in making statistical statements

In estimating the results obtained by treatment for any condition, the evidence obtained in the patients on whom the treatment was improperly carried out is not acceptable In treating cancer with the X-ray, if the dosage is too small, the results will be less satisfactory Inadequate resection of cancerous tissue gives equally poor results And so it is with these two types of treatment for thyrotoxicosis We must presume that your treatment is as satisfactory as it possibly can be, and that the surgical procedures undertaken are the most satisfactory type that can be employed It is of no purpose to refer to experiences with patients who were inadequately treated

Both radiologists and surgeons approach the subject of treatment for thyrotoxicosis from the same viewpoint, namely, that the source of the disease is in the pathologic thyroid gland Both types of treatment are aimed toward reducing this thyroid activity

It is my purpose to present the method of surgical treatment which I regard as necessary for obtaining satisfactory results and to give the results obtained by this method, then to compare these results with what the current literature has claimed for radiotherapy in the same disorder If we start with the premise that the pathologic thyroid is the source of thyrotoxicosis, surgical treatment must aim at such radical removal as to bring the thyroid function within normal limits

The normal thyroid, like most parenchymatous organs, has a large factor of safety In other words, under normal conditions, its capacity to elaborate thyroxin far exceeds the needs of the body As with other parenchymatous organs, the amount of thyroid secretion elaborated can be decreased by simple reduction of the mass of the gland Irrespective of the degree of increased secretion that occurs in the pathologic state, adequate reduction of the mass of the gland will reduce the amount of secretion so that it will be within normal limits or may even be subnormal

By using the basal metabolic rate as a measure of the activity of the pathologic thyroid gland, it is possible to control the activity of the gland with the accuracy of a laboratory experiment While the basal metabolic rate may be normal, even though there is excessive thyroid tissue present, an increased metabolic rate can be present only when there is enough thyroid tissue in the body to produce it It follows then that, when the metabolic rate fails to drop to, or below, normal following a thyroidectomy, the surgeon has left too much thyroid tissue in the body

It is further evident that, when surgical treatment is employed, one cannot logically speak of a degree or percentage of cure of a thyrotoxic individual as measured by the metabolic rate The patient is either cured or the operation is a failure The surgical treatment is never a half-way measure, the patient cannot be 50 or 75 per cent cured He must be 100 per cent cured or the operation is a failure Adequate surgical removal of the thyroid gland must result in reduction of the metabolic rate to, or below, normal The entire structure on which we base both surgical and radiologic treatment must fall to the ground if we admit of the possibility of a single exception to this statement

Total removal of the thyroid gland is not

permissible Some thyroid tissue must be left in the body It has been suggested that this residual mass can, and often does, undergo hypertrophy and hyperplasia, with resultant failure of the operation and a recurrence of the symptoms of thyrotoxicosis

It is impossible to use the terms "failure" and "relapse" interchangeably—they represent entirely different conditions The failure of an operation is directly due to removal of insufficient thyroid tissue, and must be charged against the surgeon rather than against the principle involved Although this failure is manifested by a continuation of the disease, the symptoms are less marked because there has been some reduction of the thyroid mass, but insufficient reduction

Often the condition of the patient may be so improved that he regards himself as cured A careful study, including metabolic rate studies, however, frequently will give ample evidence of continued intoxication If careful post-operative studies are not made on these patients, they are likely to be included in the list of cures Later on, when their symptoms again become more marked as a result of further hypertrophy and hyperplasia of the thyroid remnant, the conditions are regarded as "relapses" But "relapse" signifies only actual recurrence after a real cure of the thyrotoxicosis This means that the treatment employed has brought the thyroid activity to normal The patient's condition is normal for a time, then there is a return of the thyrotoxicosis as a result of growth of the thyroid mass left at operation While such relapses are undoubtedly possible, in my experience they are exceedingly rare

Careful studies show that many relapses, so reported, are simple failures caused by incomplete operation The operation which I believe is indicated in the treatment of thyrotoxicosis is radical thyroidectomy—aiming at reducing the mass of thyroid

tissue to the smallest amount which is compatible with normal or temporarily subnormal thyroid activity In practice, this has proved to be about 2 grams of thyroid tissue —1 gram on each side of the trachea In several hundred cases I have left less than this, and in about an equal number I have left from 3 to 4 grams, in an attempt to determine what amount should be left behind in order to produce a temporary hypothyroidism with a return to normal within a short period I have been disturbed by having a number of patients remain hypothyroid for a year or more, due to my having left less than 2 grams of thyroid tissue In view of these facts, I am now inclined to leave 2 grams or more in every case

In a series of 1,235 consecutive patients in whom clinical examination and raised basal rates definitely showed the presence of thyrotoxicosis, I have performed the radical operation, aiming to leave from less than 2 to about 4 grams of thyroid tissue I have been able to follow 1,096 cases for various periods

| | |
|--------------------|-----|
| Less than one year | 195 |
| One year | 288 |
| Two years | 238 |
| Three years | 163 |
| Four years | 124 |
| Five years | 47 |
| Over five years | 41 |

In 159 patients, on one or more tests following operation, the metabolic readings were found to be above normal The cause for the abnormal elevation was evident in all but a few of these patients Nine were pregnant at the time the high readings were obtained Ten had some type of infection, with elevated temperature Thirteen were taking an excessive amount of desiccated thyroid In five cases, basal conditions could not be obtained for psychic reasons In two instances the cause for the high metabolic rates was not evident, and in two others the data were incomplete In all, the

elevations were temporary, the final tests being normal (15 or below)

For varying periods 63 of the patients had elevated rates with a slow but steady drop to normal. It is my belief that more than enough thyroid tissue had been left at the time of operation. I am of the opinion that, in these cases, there is greater likelihood of so-called recurrence of the toxic symptoms.

Continued symptoms of thyrotoxicosis were evidenced by 39 of the patients. Of these, 23 consented to re-operation, which resulted in cure in 21, the basal rate dropping to normal or temporarily below normal. In the 21 patients who were re-operated upon, sufficient thyroid tissue was found present at the time of the second operation to account for the existence of the thyrotoxic symptoms. I also operated upon a considerable number of patients who had undergone elsewhere a primary operation for thyrotoxicosis. In all of these cases, also, sufficient thyroid tissue was present to account for the toxic symptoms.

At the time of the last study, 16 of the patients were thyrotoxic. In two of these, palpable masses of thyroid tissue were present in the neck some time after operation. In one patient the pyramidal process which was left at the time of operation underwent subsequent enlargement. In one patient a lobectomy was performed because one side of the gland seemed normal at the time of operation. In another case, since the patient was only 13 years old, more thyroid tissue was left than was customary.

In three of the 16 patients, normal basal metabolisms were present on two or more examinations, but after a material length of time, symptoms of thyrotoxicosis reappeared. These cases may properly be designated as "relapses." One of these was re-operated upon elsewhere. I performed a second operation on another of these patients and removed a mass of thyroid tissue weighing 15 grams which was all found on

one side of the trachea. On the other side, only a thin layer of tissue was noted. Following the second operation, recovery occurred rapidly. The metabolic rate was -34 per cent 37 days after operation.

To sum up, the results of surgical treatment in thyrotoxicosis in a series of 1,096 cases followed for various periods after operation, 1,057, or 96 per cent, became normal after one operation. Of the 39 patients who failed to become normal, 23 consented to re-operation. Of these, 21 were cured, as shown by return of the metabolic rate to or below normal. The incidence of ultimate success of radical operation for thyrotoxicosis is, then, 98.4 per cent. The incidence of failure, 1.6 per cent, is small. In view of the fact that in three of the cases palpable masses of thyroid tissue could be found after operation, and that in 21 re-operated upon masses of thyroid tissue were found, it is almost justifiable to account for all failures on the basis of faulty surgical technic and removal of insufficient thyroid tissue. The mortality in the series of 1,235 cases was 0.89 per cent. I wish to emphasize once more that, when failure occurs, it is due to leaving too much thyroid tissue at the time of operation.

There is one criticism which repeatedly has been applied to both the surgical and radiologic treatment of thyrotoxicosis, namely, that the removal of the thyroid gland does not eliminate the cause for the disease. The answer to this criticism, which adherents to both of these methods of treatment can give, is that, so far as has been shown, whatever the true source of the disease may be, the symptoms of thyrotoxicosis cannot persist when the activity of the thyroid gland is sufficiently reduced by operative or radiologic methods.

In comparing the results which I have obtained by radical thyroidectomy with those reported in the current literature for radiology, let me point out to you again that the diagnosis in all the cases included in my

permissible Some thyroid tissue must be left in the body It has been suggested that this residual mass can, and often does, undergo hypertrophy and hyperplasia, with resultant failure of the operation and a recurrence of the symptoms of thyrotoxicosis

It is impossible to use the terms "failure" and "relapse" interchangeably—they represent entirely different conditions The failure of an operation is directly due to removal of insufficient thyroid tissue, and must be charged against the surgeon rather than against the principle involved Although this failure is manifested by a continuation of the disease, the symptoms are less marked because there has been some reduction of the thyroid mass, but insufficient reduction

Often the condition of the patient may be so improved that he regards himself as cured A careful study, including metabolic rate studies, however, frequently will give ample evidence of continued intoxication If careful post-operative studies are not made on these patients, they are likely to be included in the list of cures Later on, when their symptoms again become more marked as a result of further hypertrophy and hyperplasia of the thyroid remnant, the conditions are regarded as "relapses" But "relapse" signifies only actual recurrence after a real cure of the thyrotoxicosis This means that the treatment employed has brought the thyroid activity to normal The patient's condition is normal for a time, then there is a return of the thyrotoxicosis as a result of growth of the thyroid mass left at operation While such relapses are undoubtedly possible, in my experience they are exceedingly rare

Careful studies show that many relapses, so reported, are simple failures caused by incomplete operation The operation which I believe is indicated in the treatment of thyrotoxicosis is radical thyroidectomy—aiming at reducing the mass of thyroid

tissue to the smallest amount which is compatible with normal or temporarily subnormal thyroid activity In practice, this has proved to be about 2 grams of thyroid tissue —1 gram on each side of the trachea In several hundred cases I have left less than this, and in about an equal number I have left from 3 to 4 grams, in an attempt to determine what amount should be left behind in order to produce a temporary hypothyroidism with a return to normal within a short period I have been disturbed by having a number of patients remain hypothyroid for a year or more, due to my having left less than 2 grams of thyroid tissue In view of these facts, I am now inclined to leave 2 grams or more in every case

In 159 patients, on one or more tests following operation, the metabolic readings were found to be above normal The cause for the abnormal elevation was evident in all but a few of these patients Nine were pregnant at the time the high readings were obtained Ten had some type of infection, with elevated temperature Thirteen were taking an excessive amount of desiccated thyroid In five cases, basal conditions could not be obtained for psychic reasons In two instances the cause for the high metabolic rates was not evident, and in two others the data were incomplete In all, the

again no data in the form of metabolism tests, or accurate analyses and descriptions of the clinical condition of the patients, are given.

A careful study of the German literature on the same subject has proved equally barren of that type of accurate, painstaking observations which are so characteristic of many of the German scientific investigations. None of the papers gives the results of detailed metabolic studies.

I need hardly say that I have the highest respect for the men whose work I have mentioned, but clinical research of this sort is open to criticism on the grounds stated. It must be granted that the mortality and complications of radiotherapy in thyrotoxicosis compare favorably with those of surgical treatment. Yet the apparent difference is not so great as it seems to be. The surgical mortality in those clinics in which a large number of thyroidectomies have been performed is in the neighborhood of 1 per cent, probably a little less than this. Competent surgeons, without special experience in thyroidectomy, may have an average mortality of about 2 per cent. Competent roentgenologists, in general, have a much lower immediate mortality. But what of the late mortality? The patients who are not completely relieved by radiotherapy—who have only temporary relief from their symptoms—continue to carry with them a pathologic thyroid gland. While the radiologic treatment does not produce immediate mortality, yet, with the continued thyrotoxicosis that is present in so many of the cases, there is further damage to the heart and nervous system, and marked shortening of the life expectancy.

There are but few statistical data as to length of life following either surgical or radiologic treatment. Christie's results are apparently satisfactory. A very accurate study of the goiter clinic of the Massachusetts General Hospital showed a remarkably

high late mortality, although the total number of cases included in the study is too small to permit of any definite conclusion. My own late mortality is 26 late deaths following 1,235 thyroidectomies for thyrotoxicosis, distributed as follows:

| | |
|--------------------------------|---------|
| One to six months | 4 cases |
| Six months to one year..... | 5 cases |
| One to two years..... | 5 cases |
| Two to three years | 3 cases |
| Three to five years..... | 4 cases |
| Number of years not known..... | 5 cases |

I believe it reasonable to assume that the patient whose pathologic thyroid is removed has a longer life expectancy than the one whose thyroid is still present, even though his symptoms are less marked and his metabolic rate has been reduced.

SUMMARY

Radical thyroidectomy was performed upon 1,235 patients suffering from thyrotoxicosis. But few of these patients were not completely relieved of their symptoms by the operation. Re-operation was done upon 23, and, of these, 21 were relieved as shown by clinical symptoms and metabolism tests. One patient required a third operation to secure this result.

Three patients made normal recoveries and had two or more normal post-operative metabolism tests, to be followed by recurrence of thyrotoxicosis. These cases can be properly designated as "relapses." One of these was shown to be due to inadequate removal of thyroid tissue.

CONCLUSIONS

In the hands of competent surgeons, radical thyroidectomy seems to be the most satisfactory treatment for thyrotoxicosis. The evidence presented showing the value of radiologic treatment of thyroidectomy is faulty because of failure to present adequate pre-operative and post-operative studies of the patients treated. The immediate mortality with the radiologic treatment, while

series of patients is based upon personal study, including repeated studies of basal metabolism made under controlled conditions. The state following operation was regarded as necessitating as much study as the pre-operative condition. Cases on which personal studies could not be made were excluded. The radiologic literature, on the other hand, is lacking in the presentation of material that has received this same careful study. Ample experience has shown that the activity of the thyroid gland can be reduced to normal or brought below normal by radiotherapy, and this effect can be maintained. The question arises, then, Can such results be consistently obtained? Unless they can be consistently obtained, one must question the usefulness of this method of treatment.

In a review of the literature of the last five years, but one series of cases of thyrotoxicosis treated by the X-ray is presented in which the patients have been studied with any degree of accuracy. It is the series of 305 patients reported by Groover, Christie, and Merritt (1). In this report it is stated that 305 patients were treated and that 89 per cent of them were cured. The patients were studied for a number of years after treatment, and the gains in weight and improvement in the clinical symptoms are given as evidence of the value of the treatment employed. The pre-operative studies are not stated as having been controlled. The studies of basal metabolism apparently were not made by those who gave the treatment for the condition, and no metabolic data are given.

When the diagnosis is made by practitioners, the results of metabolism tests obtained from varied sources, and the treatment given by entirely different individuals from those who make the diagnosis, the value of the evidence is greatly reduced.

The first report made by Christie and his co-workers appeared in May, 1923 (2). The

results of treatment on 114 patients were given and it was stated that 32 of them were cured. A second report (3) on these same 114 patients appeared in November, 1924, stating that 58 were cured. In other words, apparently some of the patients, at least, were under treatment for a period approximating 18 months. Obviously, when thyrotoxicosis persists for this length of time, permanent damage to the heart and other tissues of the body may result.

Jenkinson (4) presents his results in a series of cases treated by X-ray, 300 of which were observed for about four years after treatment. Although the results were apparently excellent, no data are given to permit the reader to draw his own conclusions.

The very foundation of any study purporting to demonstrate the value of any form of therapy must be first, evidence that the diagnosis is correct, second, careful observations and personal study following the application of therapy to determine what have been the results.

It requires but little experience to realize that the diagnoses with which patients are referred to specialists are often remarkable for their inaccuracy. Too often the apparatus for obtaining a metabolic rate is advertised frankly for its value in increasing the doctor's income, and not often enough for its value in making accurate studies of metabolic disorders. Even data obtained by the better class of internists not specially interested in this type of work may be faulty because their technicians have had but little experience in making such tests. This type of work should be condemned.

In a series of cases reported by Pfahler (5), all types of goiter are grouped together. From the context of his paper, there appear to have been about 500 cases of thyrotoxicosis included. He states that in two-thirds of the cases good results were obtained with X-ray treatments, but here

again no data in the form of metabolism tests, or accurate analyses and descriptions of the clinical condition of the patients, are given.

A careful study of the German literature on the same subject has proved equally barren of that type of accurate, painstaking observations which are so characteristic of many of the German scientific investigations. None of the papers gives the results of detailed metabolic studies.

I need hardly say that I have the highest respect for the men whose work I have mentioned, but clinical research of this sort is open to criticism on the grounds stated. It must be granted that the mortality and complications of radiotherapy in thyrotoxicosis compare favorably with those of surgical treatment. Yet the apparent difference is not so great as it seems to be. The surgical mortality in those clinics in which a large number of thyroidectomies have been performed is in the neighborhood of 1 per cent, probably a little less than this. Competent surgeons, without special experience in thyroidectomy, may have an average mortality of about 2 per cent. Competent roentgenologists, in general, have a much lower immediate mortality. But what of the late mortality? The patients who are not completely relieved by radiotherapy—who have only temporary relief from their symptoms—continue to carry with them a pathologic thyroid gland. While the radiologic treatment does not produce immediate mortality, yet, with the continued thyrotoxicosis that is present in so many of the cases, there is further damage to the heart and nervous system, and marked shortening of the life expectancy.

There are but few statistical data as to length of life following either surgical or radiologic treatment. Christie's results are apparently satisfactory. A very accurate study of the goiter clinic of the Massachusetts General Hospital showed a remarkably

high late mortality, although the total number of cases included in the study is too small to permit of any definite conclusion. My own late mortality is 26 late deaths following 1,235 thyroidectomies for thyrotoxicosis, distributed as follows:

| | |
|---------------------------|---------|
| One to six months | 4 cases |
| Six months to one year | 5 cases |
| One to two years | 5 cases |
| Two to three years | 3 cases |
| Three to five years | 4 cases |
| Number of years not known | 5 cases |

I believe it reasonable to assume that the patient whose pathologic thyroid is removed has a longer life expectancy than the one whose thyroid is still present, even though his symptoms are less marked and his metabolic rate has been reduced.

SUMMARY

Radical thyroidectomy was performed upon 1,235 patients suffering from thyrotoxicosis. But few of these patients were not completely relieved of their symptoms by the operation. Re-operation was done upon 23, and, of these, 21 were relieved as shown by clinical symptoms and metabolism tests. One patient required a third operation to secure this result.

Three patients made normal recoveries and had two or more normal post-operative metabolism tests, to be followed by recurrence of thyrotoxicosis. These cases can be properly designated as "relapses." One of these was shown to be due to inadequate removal of thyroid tissue.

CONCLUSIONS

In the hands of competent surgeons, radical thyroidectomy seems to be the most satisfactory treatment for thyrotoxicosis. The evidence presented showing the value of radiologic treatment of thyroidectomy is faulty because of failure to present adequate pre-operative and post-operative studies of the patients treated. The immediate mortality with the radiologic treatment while

low, is misleading in view of the shortening of life expectancy with the incomplete relief from the thyrotoxicosis which may occur in many of the cases

New Radium Discoveries Made in Canadian Northwest—Two new rich radium-bearing ore veins were discovered at Great Bear Lake, in northwest Canada, just before the winter freeze-up stopped further prospecting. Hugh S. Spence, Canadian Department of Mines expert, has stated at conferences with Washington geologists Mr. Spence as official visitor to the radium strike in Northwest Territories himself aided in the discovery of the new bodies of pitchblende ore.

Earlier reports of the rich finds of Gilbert LaBine, discoverer of the original radium ore deposits, were authenticated by Mr. Spence, who says:

"Beyond any question the pitchblende deposits at LaBine Point constitute a very valuable source of radium. At the present value of radium, ore could easily meet the \$400 per ton cost of shipment to the railroad."

More and larger amounts of pitchblende than yet found, containing, at present prices, from \$6,000 to \$8,000 worth of radium to the ton, may yet remain to be discovered, Mr. Spence predicted. Two of the veins have been traced for distances of 1,400 and 2,500 feet, respectively, and all four seem to run together like the fingers of an outspread hand.

A still larger and more valuable deposit, he said, may be at the "wrist," somewhere to the northeast of the present workings.

Another new strike of the precious pitchblende, twelve miles distant from Echo Bay where the first vein of LaBine's Eldorado Gold Mines, Limited, was located, has already been reported on the ground of the rival Northern Aerial Minerals Exploration Company.

Planes were arriving during all the time of his stay at LaBine Point on the Great Bear Lake, Mr. Spence said. These were carrying prospectors on the look-out for further silver deposits. LaBine's No. 2 pitchblende vein, interlaced with valuable native silver veins, the best so far discovered in the region, assaying some 9,000 ounces to the ton, had roused the hopes of these adventurers.

Only two men were on the ground at the time of Mr. Spence's visit, because of the freeze-up, but mining operations were to be resumed. Fourteen surface pits were being worked in the summer of 1931. The ore obtained from these by hand picking averaged 50 per cent uranium oxide, or about one gram of radium to eight tons of ore.—*Science Service*

THE MEDICAL ASPECT OF THYROTOXICOSIS¹

By CHARLES ELLIOTT, M.D., CHICAGO, ILLINOIS

THE general practitioner, through lack of opportunity to study thyroid diseases *en masse*, is frequently misled in the interpretation of symptoms referable to the thyroid. The patient who early seeks relief at the hands of his family physician may, consequently, lose valuable time before his complaint is accurately appraised and adequate remedial measures applied.

Indeed, even those especially interested in the study of thyroid disease encounter many perplexing clinical problems in the recognition of hyperthyroidism when it presents itself under one of its less frequently encountered, although none the less characteristic, clinical types.

Needless to say, in a disease process the manifestations of which are so closely bound up with the personality of the patient, it is often difficult, at times even impossible, to form an opinion as to the true status of the patient without long-continued observation and consideration.

The family physician or the general medical consultant occupies a strategic position in this respect, especially if he has a thorough knowledge of the personality and responsibilities of the patient. If, in addition he has a comprehensive knowledge of the possibilities as far as hyperthyroidism is concerned, his advice is invaluable.

Much confusion results in the evaluation of symptoms commonly attributed to thyroid disease but induced as well by other processes in which the thyroid gland may also be concerned.

The thyroid gland is an important organ in health and from that viewpoint may be considered a gland of efficiency. It plays an important part in determining the bodily reaction to mental and physical stimuli.

¹Read before the Radiological Society of North America
at the Seventeenth Annual Meeting St Louis, Mo Nov
30-Dec 4 1932

However, it does not act singly in this respect, but rather in conjunction with other vital forces in the body, including the other ductless glands and the sympathetic nervous system.

Among those about us we recognize the dull, stupid, and unsuccessful, the alert, mentally keen, and successful, and the over-stimulated, unbalanced, rarely successful individuals as representing varying grades of individual efficiency—dependent largely, as we now understand it, upon the maintenance of a functional balance of the many forces in the body, including the anatomic nervous mechanism. In all such adjustments, the thyroid gland plays a major rôle.

The normal individual who, through no fault of his own, is forced to superhuman effort in providing support for his dependents during this period of economic depression and unemployment, or the constitutionally unfit individual who assumes little or no responsibility even in normal times, may find himself worried, anxious, nervous, tremulous, sleepless, with cold, clammy, cyanotic extremities. He may complain of precordial pain, palpitation, tachycardia, weakness, and loss of weight—symptoms commonly seen in thyroid disease but manifestly not due to disease of the thyroid itself. The exact reaction picture varies with each individual and represents the unsuccessful mental and physical adjustments of that particular individual to his environment. We speak of this condition as "effort syndrome" or "anxiety neurosis."

Every individual has a limit of endurance beyond which he cannot go without manifesting symptoms similar to those enumerated. It matters not whether these responsibilities are voluntarily assumed or imposed by force of circumstances.

Our Government unwisely drafted men

from all walks of life to fill the ranks of the American Army during the World War, regardless of their mental fitness to assume military duties. As a result, the Veterans' Bureau hospitals to-day are filled with these maladjusted and unfit men, some of whom were previously able to adjust themselves, at least to the extent of self-support, but who now look to the Government for support of themselves, if not their families. It is difficult for them to realize that the war had little, if anything, to do with their present unhappy status. England, more experienced, excluded misfit recruits at the beginning of the draft.

The symptoms thus induced in the presence of a normal thyroid gland are none the less thyroid symptoms when this term is employed in the broadest sense, including associated ductless gland imbalance and disturbance of the sympathetic nervous mechanism.

We speak glibly of the symptoms of infectious diseases as being directly due to the invading organisms, whereas a little reflection must convince us that it is not the bacterial invasion, *per se*, but rather the reaction of the body as a whole to the infection which is directly responsible for the symptoms.

For example, weakness, loss of weight, tachycardia, fever, flushing, sweating, and increased basal metabolic rate, in addition to local findings in the lungs characteristic of incipient pulmonary tuberculosis, are not due directly to the tuberculous invasion but rather to the reaction of the body as a whole to the bacterial attack. The symptoms enumerated are none the less thyroid symptoms because they are observed in association with an infectious disease.

The symptoms of such conditions as effort syndrome or chronic infections may so closely simulate hyperthyroidism as to be indistinguishable from those due to disease of the thyroid itself. In fact, no hard and

fast line may be drawn between the two, and often enough men experienced in the study of hyperthyroidism may not be convinced as to the exact status of an individual patient even after long observation.

It is obvious that therapeutic measures directed at the control of hyperthyroidism in such patients—that is, those in whom hyperthyroidism may be simulated but in reality does not exist—can result only in therapeutic failure and bring discredit to the particular type of therapy employed.

The difficulty, of course, is one of mistaken diagnosis and it should be charged to the internist. In his defense, however, it must be recognized that no absolute rules can be laid down which unequivocally separate the manifestations of a latent infection an anxiety state, or a beginning or low-grade hyperthyroidism. A safe rule is to defer any therapeutic attack on the thyroid, surgical or otherwise, or indeed even the use of iodine until the diagnosis is established beyond any doubt.

A third group, which at times offers great difficulty in recognition, is the so-called thyrocardiac group. Included in this group are patients with cardiovascular manifestations not unlike those seen in other forms of heart disease but in which the usual manifestation of hyperthyroidism—the underlying cause of cardiac disability—is either obscure or entirely overlooked.

The hyperthyroid symptoms are those of long-continued, although low-grade, toxic adenoma. In contrast to the usual heart case, these patients are nervous, alert, often tremulous, with warm, moist pigmented skin, and often eye signs of exophthalmic goiter. Thyroid enlargement may be lacking, glycosuria, when present, is significant.

The basal metabolic rate is increased. A rate of plus 30 or even less, in the presence of heart disease, would be distinctive since an increased basal metabolic rate is, I believe, not a feature of heart disease *per se*.

The heart withstands the drive of long-continued, low-grade hyperthyroidism remarkably well. Often many years may elapse without enlargement. The heart tones are loud and quick, a systolic murmur is often present, hypertension may have been present for years. Later, myocardial degeneration results and enlargement occurs, the apex is found to the left rather than down. Various types of arrhythmia, particularly auricular fibrillation, may be present.

It is characteristic of the thyroid heart that it responds indifferently to digitalis but often surprisingly well to digitalis and iodine. Usually the diagnosis is delayed for years and therapeutic measures designed to control hyperthyroidism are rarely employed until after much damage has been done.

A fourth group, presenting difficulties in diagnosis, is that of hyperthyroid patients who are under partial iodine control. Iodine causes a reversal of the hyperplastic gland toward the colloid or resting state, and a more or less complete, although usually temporary, arrest of symptoms.

Iodine is used to prevent simple goiter and may be administered with good effect in all clinical types of hyperthyroidism. It acts almost as a specific, and, when administered in sufficient amounts in the control of hyperthyroid crises, it may save lives. It is, therefore, a most valuable drug to use in the control of thyroid disease.

All this is known to the general practitioner who is not averse to administering such a harmless yet potent drug to those of his patients who (he suspects) may have hyperthyroidism. His attitude is one of willingness to try iodine in doubtful cases, hoping for beneficial results.

This attitude is fallacious only insofar as it applies to the administration of iodine to patients with exophthalmic goiter in whom iodine causes a marked, although temporary, remission of symptoms. This type of goiter, however, continues in spite of iodine ther-

apy, and much valuable time is lost. As complete a remission probably cannot be accomplished by the administration of iodine at any subsequent period.

When patients under partial iodine control are first seen by a consultant, it may be quite impossible for him to form any opinion as to the patient's thyroid status. Much confusion, therefore, results. Iodine therapy should, I believe, be deferred in all cases of goiter until a positive diagnosis is made and a plan of treatment adopted. This must not be construed to indicate that iodine administration should be delayed even for an hour in the treatment of hyperthyroid crises.

Hyperthyroid crises present many difficulties in diagnosis for the general practitioner. While it is true that these patients may have had a known hyperthyroidism of some degree for years, yet the sudden onset of violent thermal, cerebral, cardiac, or gastro-intestinal manifestations in various combinations, apparently dependent, at least to some extent, upon the individual reaction of the patient, is a very serious matter indeed. Severe general infection, encephalitis, cardiac failure, or an acute surgical abdomen may be simulated. Occasionally patients in a hyperthyroid crisis, with predominant gastro-intestinal symptoms, are rushed to the hospital for abdominal section.

The diagnosis must depend upon the detection of hyperthyroidism as the background of the acute and critical manifestations. It is often difficult, if not impossible, to get a satisfactory basal metabolic rate reading in these patients during the period of crisis. The correct interpretation of such manifestations is, of course, of crucial importance to the patient, for instance, in preventing abdominal exploration and insuring the administration of large doses of iodine by mouth.

Under standard treatment the crisis will

from all walks of life to fill the ranks of the American Army during the World War, regardless of their mental fitness to assume military duties. As a result, the Veterans' Bureau hospitals to-day are filled with these maladjusted and unfit men, some of whom were previously able to adjust themselves, at least to the extent of self-support, but who now look to the Government for support of themselves, if not their families. It is difficult for them to realize that the war had little, if anything, to do with their present unhappy status. England, more experienced, excluded misfit recruits at the beginning of the draft.

The symptoms thus induced in the presence of a normal thyroid gland are none the less thyroid symptoms when this term is employed in the broadest sense, including associated ductless gland imbalance and disturbance of the sympathetic nervous mechanism.

We speak glibly of the symptoms of infectious diseases as being directly due to the invading organisms, whereas a little reflection must convince us that it is not the bacterial invasion, *per se*, but rather the reaction of the body as a whole to the infection which is directly responsible for the symptoms.

For example, weakness, loss of weight, tachycardia, fever, flushing, sweating, and increased basal metabolic rate, in addition to local findings in the lungs characteristic of incipient pulmonary tuberculosis, are not due directly to the tuberculous invasion but rather to the reaction of the body as a whole to the bacterial attack. The symptoms enumerated are none the less thyroid symptoms because they are observed in association with an infectious disease.

The symptoms of such conditions as effort syndrome or chronic infections may so closely simulate hyperthyroidism as to be indistinguishable from those due to disease of the thyroid itself. In fact, no hard and

fast line may be drawn between the two, and often enough men experienced in the study of hyperthyroidism may not be convinced as to the exact status of an individual patient even after long observation.

It is obvious that therapeutic measures directed at the control of hyperthyroidism in such patients—that is, those in whom hyperthyroidism may be simulated but in reality does not exist—can result only in therapeutic failure and bring discredit to the particular type of therapy employed.

The difficulty, of course, is one of mistaken diagnosis and it should be charged to the internist. In his defense, however, it must be recognized that no absolute rules can be laid down which unequivocally separate the manifestations of a latent infection, an anxiety state, or a beginning or low-grade hyperthyroidism. A safe rule is to defer any therapeutic attack on the thyroid, surgical or otherwise, or indeed even the use of iodine, until the diagnosis is established beyond any doubt.

In contrast to the usual heart case, these patients are nervous, alert, often tremulous, with warm, moist, pigmented skin, and often eye signs of exophthalmic goiter. Thyroid enlargement may be lacking, glycosuria, when present, is significant.

The basal metabolic rate is increased. A rate of plus 30 or even less, in the presence of heart disease, would be distinctive since an increased basal metabolic rate is, I believe, not a feature of heart disease, *per se*.

X-RAY TREATMENT IN GOITER ILLNESS¹

WITH RESULTS REPORTED AND COMMENTS MADE ON 200 INDIVIDUALLY
CONTROLLED CASES

By ALDEN H WILLIAMS, M.D., FACP, GRAND RAPIDS, MICHIGAN

THE literature on hyperthyroidism and the thyropathies presents a wide variation of opinion. The cause of goiter illness, accepted by many, is abnormal activity of the thyroid cells. Emphasis on autonomic imbalance, as a factor, is made by a goodly number. The belief that one is predisposed to the illness by a lack of iodine is quite generally accepted, but some think calcium excess is a predisposing cause, and iodine deficiency of minor importance. We are told that iodine benefits both toxic adenoma and exophthalmic goiter. Then again we are informed that iodine is of no value in toxic adenoma. Some good authorities state that there are no contraindications to surgery, others say this idea is very much open to question. In the one opinion, radiation therapy is temporizing, and curative in the other. The cause of goiter illness begins in the thyroid or elsewhere, subsequently upsetting the thyroid. Goiter histopathology is, or is not, consistent with symptom complex. The thymus has, or has not, anything to do with the disease. Graves' disease and toxic goiter are described as different diseases, or the same disease in different stages, or the same disease with different constitutional sensitivities. Writers emphasize the immediate dramatic cure of symptoms by surgery—others question the cure by reporting a large percentage of sick patients a year or more later. Some institutions emphasize immediate low operative mortality, with recurrences given repeated subtotals and kept out of the morbidity statistics as long as possible.

A well-known neurologist reviewed a

group of over a hundred thyroidectomies and reported myxedema symptoms in over 20 per cent of the cases two years after operation. An internist states, in his book on the non-surgical treatment of goiter, that 30 per cent of the cases that enter his institution for treatment come with a thyroid scar.

All of this contradiction opens a fertile domain for the radiologist to appraise and lures him to chart, in his own field, a course that may lead to a clearer conviction of the successful treatment and end-results.

HYPERTHYROIDISM

Although the exact etiology of hyperthyroidism is not known, it is most probable that thyroid cell activity is an important factor in the cause. If all thyroid cells are removed, normal body activity is crippled.

Surgical, medical, or radiation management modify the clinical picture of hyperthyroidism. If we are treating goiter illness by one method and know nothing of the problem of other methods, we should feel a sense of inadequacy and bewilderment.

Accepting then, as a working hypothesis that goiter illness, known in some of its variations as hyperthyroidism, toxic goiter, and exophthalmic goiter, is caused by excessive or altered secretion of the thyroid gland, we may expect methods which inhibit or destroy function to be curative.

RADIATION TREATMENT

As agents, surgery and radiation have much in common both abolish function in a subtotal degree. Results seem to be very similar in cure statistics. It is said that

¹Read before the Radiological Society of North America at the Seventeenth Annual Meeting, at St. Louis, Missouri, Nov. 30-Dec. 4, 1931.

soon pass and treatment of the underlying hyperthyroidism may proceed as usual

Needless to say, no patient should be subjected to therapeutic measures directed to-

ward the modifying of thyroid activity unless the physician has, first, a clear-cut conception as to what part, if any, the thyroid may play in the production of symptoms

River Improved to Bring Radium Ores to Civilization—Eight hundred miles of waterway linking rich radium discoveries with civilization are being improved by the Hudson Bay Company in order that valuable ores newly discovered in the Canadian Northwest Territories can be transported out of the wilderness

The radium ores are worth \$70,000 a ton at present prices and silver ores found in the same workings assay \$3,000 a ton

Airplanes have been used to carry prospectors and miners back and forth, but it will be

more economical to carry the heavy ore by water. Twenty tons of ore were brought out last Summer, but the difficulties were great

Most of the improvements are being made on the Great Bear River, the outlet from Great Bear Lake, on which are situated the new mines. The Great Bear River leads to the Mackenzie, down which some 7,000 tons of freight are carried in the tur steamers each year. One ten-ton scow is the only means of transport at present on Great Bear Lake itself.

—*Science Service*

and follow-up records Some of these incomplete cases may be good for later study Cases of simple thyroid enlargement, without symptoms of illness, are not here considered They may be relegated to a prophylactic study or to cosmetic surgical therapy

There were so many borderline and atypical and mixed cases that I did not feel comfortable in classifying them in definite groups I realize my consideration of the 200 cases generalized as *goiter illness* is also open to some question A few cases were errors in diagnosis in which treatment was started for hyperthyroidism, which may not have been present They were disguised cases and did not check true as we went along, treatment being early discontinued with less harm, I hope, to the patient than might have followed had the error been an operation

A few other cases were thrown out because of abortive treatment brought about by change of mind of the patient, pressure of neighbors, or decision of the surgeon that operation was imperative

In comparing statistics of cure given by different radiotherapeutists, one is puzzled by the great divergence of claims This may be explained possibly by the different types of thyroid illness and the varied severity found in different localities

EXOPHTHALMIC TYPE

In our group of 200, there were 34 cases clinically of the *exophthalmic type* (Figs 1-4 1-B)

Cured, $70^{30}/_{34}$ per cent

Improved, $17^{22}/_{34}$ per cent

Unimproved, $11^{16}/_{34}$ per cent

This tabulation compares favorably with the cure analysis of the whole group

The four failures show the following human documents which are recognized because of familiarity

1 Socially inclined—persisted in parties and nightly movies There was no improvement after four treatments, and the patient was sent to operation

2 The patient, who would not have his abscessed teeth extracted, was told not to return until this had been done (did not come back)

3 This patient is the busy proprietor of a store and insists on fishing and hunting He will not accept his limitations and is still not well

4 In this case, there is some emotional conflict disharmony at home The patient needs a neuropsychiatrist Diagnosis is clouded

Of the six improved cases, two suggested neurasthenic possibility, being worse in the morning and at no time very ill

In the 24 exophthalmic cures (Fig 2) were some of our most desperate cases, and brilliant results, among them were three extreme mental cases of the confused type which became normal and have remained so over the three-year period of our follow-up study

Perhaps in thyroid illness, all statistics should use the word "rehabilitation" instead of "cure," and yet, if the patients are relieved of all symptoms upon which was

| Average basal metabolism at end of treatment (108 cases)..... | +16 |
| Average time (in weeks) before improvement commenced..... | 3.3 |

either method will cure from 50 to 75 per cent of all cases and produce satisfying improvement in from 15 to 25 per cent more.

In this study, I do not wish to set up one method against the other, but to give my own experience of radiation management, and some few comments based upon my observation and survey of surgical treatment, which may broaden the judgment and appraisal of both methods. My hope is that, as time goes on and further work is done in all fields the accumulation of cases, by tolerant and sympathetic collaboration, will reconcile differences and balance the elements of the problem. As the radiologist views this problem, he regrets that in some books, and at some goiter conferences on the general consideration of treatment of thyroid disease, so little space is given to the method of irradiation.

The aim of any treatment is the cure as soon, as permanently, and as surely as possible, and while doing it, to give the patient as much comfort and activity and safety as available.

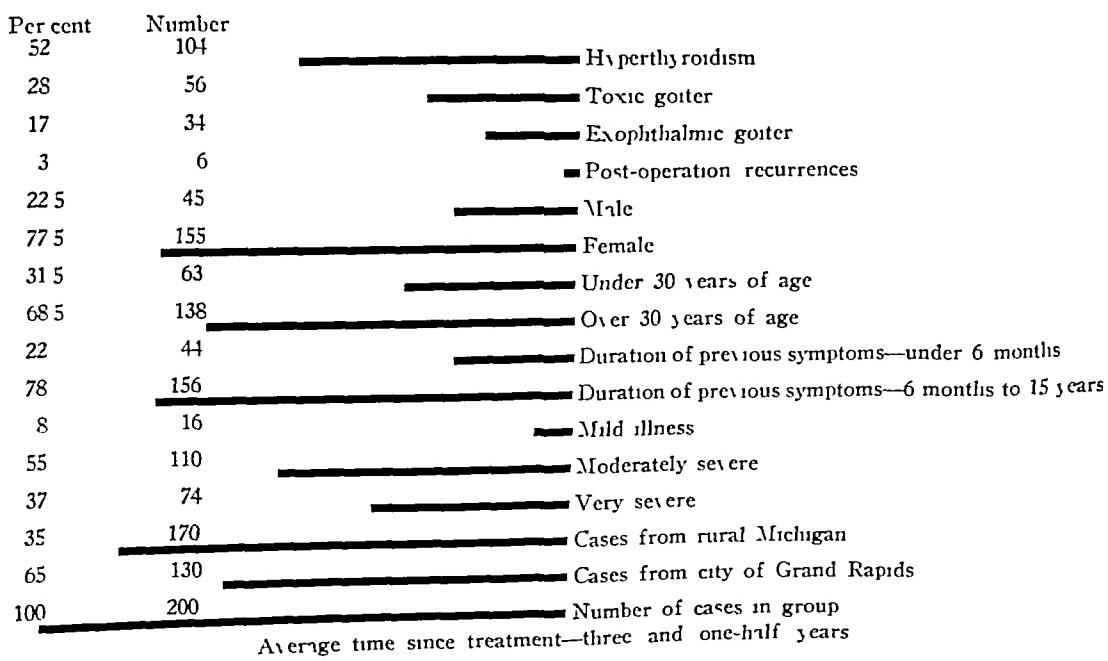

I have been interested in the radiation treatment of thyropaths for 15 years. The longer I have watched results and the more I have followed reports of other methods, the more courage I have accumulated to make this report.

GROUP MATERIAL

In discussing material, it seems impossible to avoid the subject of classification. All of the 200 cases may go, if we wish, under the inclusive class of hyperthyroidism, with decision based upon carefully checked elevated basal metabolism. As in the usual report, subdivisions of toxic goiter and exophthalmic goiter have been arbitrarily made upon consideration of age, onset, symptoms, and physical examination.

The material (Table I) is consecutive and unselected except that, instead of using a larger group of 258 cases, some of which were incomplete, I did elect to throw out 48 cases deficient in preliminary examination, basal data, pulse, weight, progress notes,

based the diagnosis of goiter illness, why are they not cured?

In looking over this exophthalmic group, we recognize the controversy aimed at both surgical and roentgen treatment. Without

are vacillating in confidence and need to be frequently realigned and reassured. This is the point at which we failed in the cases that gave up treatment and went to operation, even when they were improving.

Fig 1-A (left) A patient presenting the exophthalmic type of goiter. Before treatment, the weight was 110 pounds, pulse 120, and the basal metabolic rate + 50.

Fig 1-B (right) Same patient is shown in Figure 1-A, after treatment. The weight was 133 pounds, pulse 84, basal metabolic rate + 15.

results to back us up, it might seem illogical to treat or remove surgically an emotionally activated thyroid when a causative mental conflict remains. Possibly we are reversing the rotation of a vicious circle by lessening the hyperthyroidism, which diminishes sensitivity and nullifies the conflict. This lessened conflict, having a diminished stimulation on the thyroid, pyramids the benefit.

In this exophthalmic group, we made a special effort to take plenty of time with quiet visits and personal questioning. The cases seem to be practically unanimous in suggesting a neuropathic personality. They

One radiologist advocates treating by X-radiation only those cases which, by personal conviction, prefer irradiation. I would say if we, ourselves, have a firm belief that a line of treatment is indicated as best and safest, it would seem part of our duty to spread this belief before such a patient if necessary, and to have no lack of courage in commencing and continuing treatment.

The surprising triumph in many cases is not only the change in appearance and personality, but in the confidence toward the treatment as time goes on. Patients be-

come easier to influence and more logical to manage

HYPERTHYROID GROUP

In the hyperthyroid (Fig. 3) group of 104 cases, there were 10 adolescent goiters with increased pulse and basal rate, as the main excuse for treatment. These received an average of four treatments, before becoming normal.

One young girl in this group, who exhibited no imperative symptoms and had a basal metabolism under +20, went to operation two days after our initial treatment. I saw her a year later, with marked symptoms of subthyroid ill-health. A surgeon has no excuse for a hurried diagnosis, for he knows his thyroidectomy is irrevocable.

The number of cases classified as toxic goiter (Fig. 4) made a group of 56, with an average long history of previous attacks and recent flare-ups. These cases represent chronic illness in the later decades of life with variable visceral damage. That is why no quick cure in this type should be expected.

TREATMENT AVERAGES

The average time for the appearance of improvement in symptoms was three weeks, or after the third treatment. This explains why the Holmes group were disappointed in radiation therapy. They arbitrarily made their decision to give three treatments and, if no improvement was apparent, to refer the case to the surgeon. This is like advising roentgen treatment only in pre-surgical cases.

There were several cases with discouragingly long durations of symptoms and treatment, four cases receiving over 25 treatments in seven months, but with complete recovery, and no over-treatment residue.

Treatment is discontinued if the basal rate is near +15 and the weight has increased and the pulse returned to normal.

Of the cases that came to us for irradiation, 3 per cent were post-operative recurrences. Israel Bram, of Philadelphia, reports that 30 per cent of the cases coming to his institution are post-operative.

We reported one of our six post-operative recurrences as a radiation failure. It is a questionable point to decide that the final effort in the case shall assume the entire odium of failure, or flaunt the full credit of success.

We radiologists see the surgeon's failures and he sees ours, and the medical man sees both. Refractory cases in any field need co-operation, and the collaboration of all methods of treatment. One surgeon states that any treatment other than operation is contra-indicated in goiter, because of delay and malignancy possibility.

Carcinoma developed in two of our cases, or 1 per cent.

I have tried to understand the apparent hostility of surgical organizations to other than operative management. I cannot feel that it is imaginary on my part, or, on their part, instinctive competitive guarding of their own field. Radiologists are seldom placed on programs by surgical organizations to discuss their experiences in treating goiter. It may be the surgeon's lack of understanding of radiation treatment and its results, or a natural suspicion of the new, untried, and unknown.

SOURCE OF PATIENTS

Our group had a larger percentage of toxic goiter type than the usual group reported. In trying to analyze this, I find that the greater number of these cases were not referred by physicians or surgeons, while, on the other hand, the majority of the exophthalmic type were cases which had been referred. The roentgen therapist, consequently, is limited in cases referred to him by the decision of his medical and surgical colleagues—that toxic goiter is surgical.

This limitation and clipping of wings is especially true of the full-time salaried hospital radiologist. Hospitals are usually surgical, and in them, instead of the internist be-

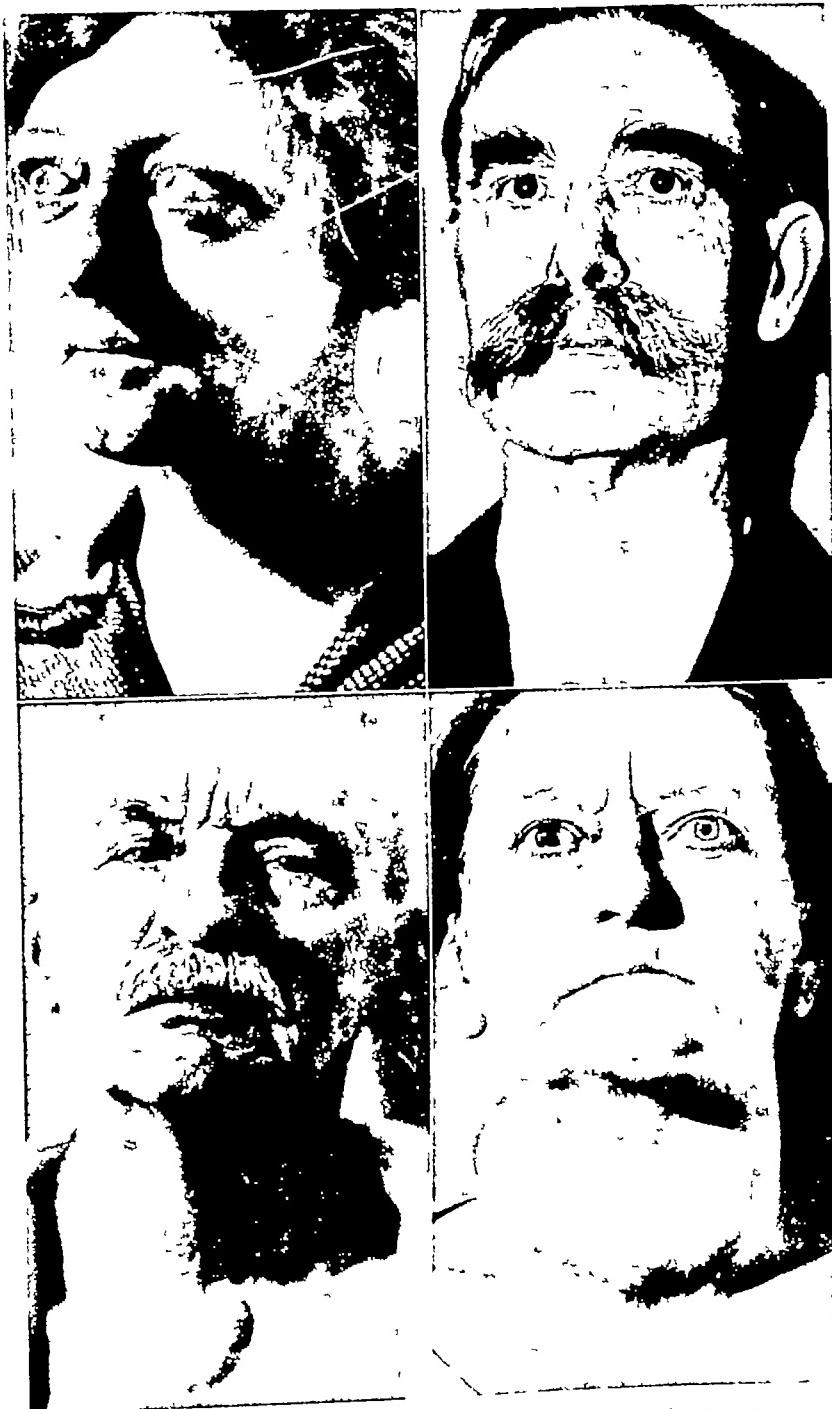

Fig. 2 (upper left) A typical member of the exophthalmic group

Fig. 4 (lower left) A membe

Fig. 5 (lower right) A case of toxic

ing judge as to the proper treatment régime to be carried out, the surgeon holds dominion over all.

To cloud the issue spontaneous recovery has been suggested as a factor in the radiologic cure, but it seems to me too rare in a mixed group of patients with thyroid illness to be accepted. Improvement under radiation treatment is too uniform to be considered spontaneous. Non-treated, or scientifically neglected cases, do not have a parallel cure percentage.

WEIGHT

The weight gain, as noted often by others, was the best guide to a decision of improvement. Patients who have had a great loss of weight before beginning treatment may be expected to gain the most before being cured. We report an average gain in 165 cases of eight pounds, a loss in 29 cases of 43 pounds, with no weight changes in six cases.

PULSE

The pulse, which, too, is a fairly dependable symptom for diagnostic decision, is also a good calibration of improvement. We report a beginning average pulse rate of 105 in the 200 cases, a decrease of 24.2 beats in 181 cases during treatment, 17 cases showed an average increase of 8.5 beats, and two cases showed neither gain nor loss. The almost uniform improvement of pulse rate during treatment is significant and gives one the comforting feeling that some change for the better is going on.

DURATION OF TREATMENT

The number of treatments required varied, ranging from four to 29 over a period of from six weeks to 10 months. The average number of treatments per case in our group of 200 was 10.74, and the

average time under treatment was 3.65 months.

In studying alone the 74 more severe cases in the group, I find that there were 82 per cent which became well and stayed well for the average of the 4.6 years follow-up period to date. So it would seem that in the group of the worst cases may be found the most striking indication for roentgen treatment.

BASAL METABOLISM

We feel that the basal metabolism is so important as a valuable link in doubtful cases, and as a quantitative element in progress of treatment, that we have thrown out of our study all cases having incomplete basal records. This has left consideration of a smaller group, but I think it has given a greater confidence in possible conclusions.

Basal reports are by no means infallible. One should bear in mind that rapidity of breathing alone raises the basal reading. Remember, also, that the rate has a different meaning, whether the case is spent or on the up-grade. One should own a metabolismeter and know its calibration and peculiarities after many normal clinical checks. One should make the test himself, if in any doubt of the tact and experience of the assistant or technician, and never fail to inquire into the deportment of the patient during the 12 hours preceding the test. One may find that a small cup of coffee, or a bit of toast, or a long walk has been indulged in.

The average basal metabolism of 200 cases at the beginning of treatment was +49, at the end of treatment, +16, showing a grade and constancy of reduction too uniform to be assigned to any predominating cause other than radiation treatment itself.

RECURRENCES

We had eight cases which recurred after one year, or 4 per cent. I must admit here

TABLE III — TREATMENT RESULT

| Per cent | Number | Cases studied averaging 3½ years since radiation treatment |
|----------|--------|--|
| | 200 | |
| 80.5 | 161 | Cured |
| 13.5 | 27 | Improved |
| 6 | 12 | Unimproved |
| 4 | 8 | Recurrent after one year |
| 2.5 | 5 | Went to operation |
| 0.5 | 2 | Developed myxedema |
| 0.5 | 1 | Developed telangiectasia |

TABLE IV — MISCELLANEOUS OBSERVATION IN GROUP MATERIAL OF 200 CASES

| Per cent | Number | |
|----------|--------|--|
| | 200 | Group material |
| 26 | 52 | Emphasizing focal infection factor |
| 18.5 | 37 | Emphasizing overwork as possible factor |
| 13 | 26 | Emphasizing fear and worry as possible factors |
| 9 | 18 | Emphasizing family disharmony as possible factor |
| 18.5 | 37 | Showing gastro-intestinal symptoms |
| 15 | 30 | Showing subjective heart symptoms |
| 6.5 | 13 | Showing hypertension |
| 6 | 12 | Showing severe heart damage |
| 4 | 8 | Associated with fibroid |
| 4 | 8 | Associated with marked mental symptoms |
| 3.5 | 7 | Associated with low grade fever |
| 2 | 4 | Associated with diabetes |
| 1.5 | 3 | Associated with persistent hoarseness |
| 1 | 2 | Associated with carcinoma in thyroid |

that on re-study I removed three cases from the relapse statistics because their secondary rise of symptoms occurred a few months after treatment and within the year usually allowed for cure. In these three cases, the pulse and basal rate showed the treatment was not sufficient when it was interrupted. Recurrent cases usually respond readily to a further short course of treatment.

Recurrence is a characteristic of thyroid illness (Fig 5) and should not worry the reporter of thyroid statistics. Nor should the therapist view it with unusual concern,

for a few more radiation doses will usually bring on permanent recovery.

At the Interstate Convention in October, Dr Frank Howard Lahey, of Boston, said "If my patient does not get well, I know I have not taken out enough thyroid." Thus could the radiologist say, if he wished "I failed in that case because I did not give enough treatment. The failure is not in the method of irradiation, but in my deficient technic." Our failures were 12 cases, our improved cases numbered 27, and our cures totaled 161 (Table III).

It is satisfying to feel that patients cured by radiation still have a thyroid gland left in case the body needs it for future endocrine balance. The gland has not been destroyed, but more or less inhibited according to need.

TECHNIC

Our roentgen technic has changed only in a minor degree in the last 10 years. In the usual cases the factors are 125 K V P, 36 cm F S D, 3 mm aluminum filter, 5 ma. current, one area 10×12 centimeters. The dose is repeated weekly, or at 10-day intervals, for an average of 10 doses.

The factors which are changed slightly, as the case suggests, are focal skin distance and increased fields in large goiters. The time is decreased in sick and hypersensitive cases. The spacing of treatments is extended in mild cases. The number of treatments is cut down, if improvement starts early.

In stubborn cases, we do not change the factors, but have no fear in extending the number of treatments over a period of from six to seven months.

We aim to give from a 40 to 55 per cent erythema dose. As is known, this would vary the time factor in different equipments. One should get his own so-called erythema dose by skin test and then measure the same dose in r units, so that technic may be duplicated. We have two machines which, checked by sphere gap, differ 10 per cent in kilovolt peak factory calibration.

IODINE

A few years ago in some of our cases we used iodine as an aid to roentgen therapy. The check-over showed 11 iodine cases, out of 25 studied, to have been apparently more stubborn than the expected average. We have discontinued the use of iodine, but feel

that a difference of opinion might be tenable by other workers with larger groups. Like many other goiter problems, the iodine question is still open. I suspect we have neglected other drug possibilities in our faith in roentgen therapy.

A vast number of articles (enough to equal these pages in bibliography) has been written on the consideration of thyropathies in the last five years. Of these, 156 have been examined and the titles are alphabetically appended. Clinically, sufficient proof of the value of irradiation would appear to have been established.

Thyroidectomy, as the exclusive best treatment for hyperthyroidism, is being challenged in many quarters to-day. Results claimed for it vary from 18 to 92 per cent of cures. Careful study of later post-operative results, therefore, is needed to clear up (Fig. 6) the question. Almost all of the reports in the surgical and radiologic fields, including this report, have neglected medical and neuropsychiatric consideration.

What treatment to be advised for each patient is a real medical problem—the circumstances of the patient may require a compromise.

The surgeon has a difficult decision to make. He wonders how much thyroid tissue to leave, and what is the physiologic status of this tissue which he has sewed back into place. He does not want to substitute permanent myxedema for a possible temporary hyperthyroidism. He knows that the proper subtotal will give good immediate improvement, but he wants also to know that the patient's health in years to come will be open to no serious doubt. He cannot call cured his post-operative patients with subthyroid illness.

I sympathize with the surgeon when a questionable case insists upon an operation. The surgeon knows, after operation, he has no retreat from a wrong diagnosis. I also sympathize with him when a post-operative

case returns for another radical removal, and there is *nothing*, or only a fraction of a gram, to remove. Exploration for aberrant misplaced thyroid tissue leaves him still in difficulty (Fig 7).

There are many patients who would be

understanding among physician, surgeon, and radiologist. We cannot question the conscientiousness and earnestness of one another's work. To learn the best for our patient is our aim, and this will not come through rivalry of different methods of cure,

Fig. 6 (left) A case which exhibited an unusual post-operative scar
Fig. 7 (right) A patient suffering from post-operative subthyroid illness

good material in point of courage or patience for either a surgical or roentgen treatment group, who have no positive indications or contra-indications in either direction. If one has confidence in his own method, he has a good brief for helping such a patient to decide. He has, however, neither the sporting nor ethical right to discredit another's method—little known to himself.

The object of this review has been to add, if possible, something to the general appraisal of the value of radiotherapy in the treatment of goiter illness.

Symposia on goiter should foster good

but by the collaboration and co-operation of all.

SUMMARY

We have pointed out the variation of opinion surrounding the field of goiter and its treatment. Based upon the theory of depressing a hyperactive gland function, we have shown our conviction of the value of radiation treatment. After an extended follow-up observation, 200 cases are reported. Classification of group material, treatment technic progress and final cure results are discussed. Cases averaged 10 treatments over a period of three and one-half months.

The average drop in pulse was 24.2 beats, average gain in weight, 8 pounds, and lowering in metabolic rate, 23 points.

One hundred and sixty-one cases, or 80.5 per cent, were definitely cured.

Twenty-seven cases, or 13.5 per cent, were improved, making a total of 188, or 94 per cent, either cured or improved (Table III).

Eight, or 4 per cent, recurred after one year, five of which were later re-treated and cured.

Only two cases, or 1 per cent, developed subthyroid symptoms, and only one case, or 0.5 per cent, showed telangiectases.

The importance of unhurried diagnosis and frequent metabolic rate check is emphasized.

CONCLUSION

1 Our own work as here reported has entrenched us in the conviction of the value of irradiation in goiter illness.

2 The bibliography has convinced us that thyroidectomy as the best treatment is open to serious question.

3 We feel certain that the hyperthyroid patient, as a primary problem for the internist, has been underemphasized, and that statistically much is to be desired in diagnosis and follow-up records, so that surgeon, radiologist, and internist may read and speak in the same clinical language, with better understanding, less rivalry, and more collaboration.

Invents Tiny Apparatus to Regulate Radium Treatment—A tiny apparatus hardly larger than a pea, so small that it can be introduced into most cavities of the human body, has been devised by Dr Louis Mallet, head of the laboratory of the anti-cancer center of Tenon Hospital, Paris, to help physicians measure the amount of radiation that reaches various organs and parts of the body during radium treatment. The apparatus has been described in a report made to the French Academy of Sciences. It consists of a small metal knob, the size of a pinhead, within a slightly larger metal enclosure. The air between the two does not conduct electricity under ordinary conditions, but becomes conducting under the influence of radium. Such a tiny chamber is first screwed onto an apparatus which charges it to about 160 volts. Then

it is introduced into any part of the body, such as the throat, which is being exposed to radium. After a given time the ionizing chamber is taken out and its loss of voltage measured. This gives a measure of the intensity of radiation to which the chamber has been exposed in the body, and consequently, of the amount of radiation to which that part of the body has been exposed in the given time.

Dr Mallet is already known for his invention of a similar device which is used in many hospitals for measuring indirectly the strength of radiation employed in cancer treatment. The advantage of the new method is that one or more of the ionizing chambers can be introduced directly into the body, and that they can be sent out to be used by physicians and afterwards returned to a central laboratory for measurement.—*Science Service*

THE RADIOLOGIC ASPECT OF THYROTOXICOSIS¹

By LEON J MENVILLE, M.D., F.A.C.R., NEW ORLEANS, LOUISIANA

IN the surgical fraternity it is common to hear depreciation of the treatment of thyrotoxicosis by radiation therapy. It is said by some that, because surgery has been shown to offer a large percentage of cures with a low mortality rate, there is no need for any other method of treatment. In a few large surgical clinics of this country, excellent results have been obtained in the treatment of toxic goiter by operation, with a low mortality rate. Unfortunately, such brilliant results are not representative of those obtained by the general surgeons, who are, perhaps, competent in other fields of surgery, but lack the skill and experience so necessary in goiter surgery. Perhaps their attitude of opposition to radiation therapy would be altered if reliable statistics could be obtained on the number of cures, improvements, failures, and deaths following operation for toxic goiter by the general surgeon. If it were possible to procure such statistics, no doubt a certain number of cures and a surprisingly large number of failures and deaths would be revealed.

In one of the largest surgical clinics in America, 10,781 cases of simple toxic and exophthalmic goiter were operated on during the period from 1924 to 1930, inclusive, with a mortality rate of 1.17 per cent. This small percentage of deaths is truly remarkable and speaks well for the great skill of certain American surgeons, who, on account of their wide experience in goiter operation, have become experts. If such a low mortality rate represented the results obtained by general surgeons throughout this country, there could be but a slight argument for any other form of treatment. Unfortunately, this mortality rate does not prevail.

MacLean (1), in 1921, made a survey to ascertain the surgical mortality in exophthalmic goiter, sending questionnaires to 100 American and Canadian hospitals. The replies indicated that a mortality rate of 8 per cent existed at that time. Some time later, he sent questionnaires to 200 additional hospitals, and obtained about the same percentage, the mortality rate being then 7 per cent. In 1929, Cooke (2) stated that there was a general increase in surgical mortality rates during recent years, and that thyroid surgery headed the list, with a mortality rate which had increased 250 per cent in the preceding two decades. He believed the reason for this increase to be that every local surgeon to-day operates on goiter cases, while several years ago operation was done by only a few experts.

There are many causes which produce deaths during and following surgical operation for toxic goiter, which have been divided into immediate and post-operative causes.

The causes for immediate deaths, according to C. Mayo (3) are:

- 1 Hemorrhage
- 2 Air embolism
- 3 Myocarditis
- 4 Suffocation or the anesthetic

The causes of post-operative deaths are:

- 1 Pneumonia
- 2 Sepsis
- 3 Tetany, or myxedema

Recent animal experimental work by Nordland Hall, and St. Cyr (4) has shown that air embolism is a possible cause of sudden death during thyroidectomy. They state that "a patient with toxic goiter is much more susceptible to fatal air embolism than a patient with non-toxic goiter."

¹Read before the Radiological Society of North America at the Seventeenth Annual Meeting at St. Louis Nov. 30-Dec. 4, 1931.

In reviewing the causes of death during and following operation, we find that myxedema is the only one which could be produced by radiation therapy, and it is only on the rarest occasions that this occurs. No stronger argument could be advanced in favor of radiation therapy in the treatment of toxic goiter than the dangers encountered in the surgical treatment of this disease.

There was a time when gastric and duodenal ulcers were regarded as purely surgical conditions. At the present time, however, many of these ulcers are being cured by non-surgical methods. So it is with toxic goiter. For a long time the treatment was medical, then surgical. At the present time, both methods are used, and, since the addition of radiation therapy, the need for surgical operation and the mortality rate have been markedly lessened.

Radiation therapy is now considered by the better informed members of the medical profession as indispensable in the treatment of certain kinds of goiter, as is surgery in other types. Bardachzı (5) says "Roentgen therapy has become as indispensable a part of the treatment as surgery. Irradiation with a correct technic is free of danger and the mortality after operation is from 3 to 4 per cent. There is about 20 to 30 per cent recurrence after surgery and only 10 to 20 after irradiation."

The excellent results obtained in the treatment of toxic goiter by irradiation are not alone due to the changes produced in the gland when it is in a state of hyperfunction, but they are also thought to be due in a measure to the irradiation of the thymus gland. It is presently believed that the thymus gland undergoes certain changes in cases of thyrotoxicosis, and also that the benefit received in post-operative hyperthyroidism by radiation therapy is probably due, to a certain extent, to the irradiation which the thymus gland receives. Schwarz (6) recommends that the thymic region should

be included in the field of treatment while irradiating the thyroid gland, and that the larynx and trachea should be protected.

The normal thyroid gland is not considered radiosensitive by some authorities, and the effect of irradiation is manifested only when the gland is in a state of hyperfunction.

Meyer (7) concludes from animal and clinical observations "The thyroid gland belongs rather with the group of radioresistant than with the radiosensitive organs." He also states "From the viewpoint of pathology as well as from the clinical observation, an adenoma, or newgrowth of the thyroid, in which the cellular elements are increased, is more sensitive to radiation than a cystic or colloidal tumefaction." This may account for reported failures of radiation therapy in certain types of goiters. However, Holzknecht (8) states that the action of the X-rays results in inhibition or depression of the growth and function of the cells. X-radiation cures in hyperfunction and secretory hyperplasia in the same way as does surgical reduction.

Very often the statement is made that an irradiated thyroid gland becomes difficult to remove by operation because of adhesions, believed to be due to radiation therapy. Because of the lack of experimental evidence substantiating this belief, we are sometimes inclined to think this is, in many instances, simply propaganda against the use of radiation therapy in the treatment of toxic goiters. Soiland, Costolow, and Meland (9) say that reports from prominent surgeons and pathologists have discredited the belief that irradiated thyroids are more difficult to operate. They say

The general agreement is that it is impossible for the surgeon and pathologist to pick out cases which have had previous irradiation. Difficult operation is often met with in cases in which there has been previous thyroiditis.

with fibrosis, so some of the operative difficulties ascribed to radiation probably have no relation to previous irradiation. However, if the cases are properly selected for irradiation, it is very seldom that surgery will ever be needed.

In this regard, we find that Holzknecht (10) says "Only those patients suffering with Basedow's disease should be operated on who do not respond to roentgen rays, cases with large struma, compression of the trachea, or very acute cases of Basedow's disease which do not respond favorably to radiation. Following moderate doses, there are no adhesions formed to render a future operation difficult." This factor has been ruled out by statistics which prove that the adhesions, if found, were already there before the treatment and that they occurred in untreated as well as in treated cases.

We radiologists have known for many years that we have in radiation therapy a valuable agent with which to treat toxic goiters. We also recognize that the percentage of cures has been, in fact, high when compared with that of surgery, and with practically no mortality. We know that, in thyrotoxicosis, the results from radiation therapy would be greatly improved if the medical profession could be made to appreciate that the radiologist should be given the same latitude as the surgeon in treating these cases. Many radiologists have experienced the unpleasant situation of having a case of goiter referred for radiation therapy, the referring physician, at the same time, treating the patient medically, often being the one to instruct the patient when, and when not, to take radiation treatment. It would seem that the physician simply lends his patient to the radiologist. This lack of co-operation not only confuses the radiologist, who is often uninformed of the nature of this outside treatment, but offsets the good he could accomplish if the patient were kept

under his constant personal supervision. It is high time for the radiologic profession to assert itself in this regard. This can best be accomplished by educating the medical profession through presenting to it irrefutable statistics showing the high percentage of cures and improvements, with practically no mortality, when cases of thyrotoxicosis are treated by radiation therapy, and also the large number of cases treated by the radiologist which had previously been operated on. Perhaps in this manner they will be made to appreciate the great value of radiation therapy and will realize the need for closer co-operation with the radiologist.

In order to obtain such statistics, questionnaires were sent to 200 radiologists, some of whom were practising in large cities, some in small cities, and others in towns and rural districts. In this manner, we hoped to receive replies which would be representative of the results obtained by radiologists of varied experience with radiation therapy in goiter. Such statistics would be different from the usual surgical statistics which often represent the results of some skilled surgeons at a large surgical center and do not always represent the experience of the general surgeon.

At this time, 75 replies, representing 38 states, have been received. The smallest number of cases treated was 3 and the largest number was 1,500. Out of the 75 replies, 27 stated that they had either lost their records, or did not use radiation therapy in the treatment of goiter. The replies indicated that the method of distribution was very fair and should make this report an interesting one for statistical study.

In order to facilitate the study of the replies received, we have grouped them in eight classes, including one table. A study of the various divisions discloses some interesting data. Groups 1 and 3, with the smallest number of cases (63 and 328 respectively), show the lowest percentage

of cures, whereas Group 8, with the largest number of cases (3,270), shows the highest percentage of cures. However, the average of all the groups is high.

Out of a total of 10,541 cases treated by radiation therapy, 980 had previously been operated on. The percentage of recurrences is low and should compare favorably with that of surgery. In fact, a superficial search of the medical literature indicates that recurrences after surgery are placed by some at from 20 to 30 per cent, however, in this series of 10,541 irradiated cases, it was only 8.45 per cent.

It must be concluded from this statistical study that radiation therapy is a safe form of treatment in thyrotoxicosis and the percentage of cases is comparable with that of surgery, the recurrences being perhaps less. This survey clearly shows that radiologists

are capable of satisfactorily treating cases of thyrotoxicosis, and that the splendid results obtained with radiation therapy are not restricted to a few radiologists of great experience but are general among the radiologists of this country.

It should, therefore, be appreciated that radiation therapy at the present time offers more to certain goiter patients than any other form or forms of treatment. Myxedema is the only one of the many immediate and post-operative causes of death to such patients when operated on which can be produced by excessive radiation therapy, and this happens only occasionally. For this reason, radiation therapy is the safest of any single method of treatment. It offers as high a percentage of cures, with less percentage of recurrence, and its economic consideration is of importance. Patients are

relieved of hospitalization, with its attending expense, along with the mental anguish of an approaching operation. Then, again, should operation be deemed imperative, after irradiation, there can be no contra-indication to such a procedure. But if care is exercised in selecting goiter cases for irradiation, there will seldom be need for operative interference. We believe from general observation that there is indication for the use of surgery in certain types of goiter, we are

also convinced that, if radiation therapy were used whenever it is indicated, many lives would be saved and a very large percentage of such cases cured.

This report is a convincing demonstration of the fatuity of the notion existing among certain members of the medical profession, that radiation therapy will allow itself to be overlooked in the treatment of certain types of goiter. On the contrary, we have irrefutable proofs of its efficacy in the treat-

ment of thyrotoxicosis, and we are hopeful that the medical profession will soon realize its merits in a more general way

Measurement of Electron Rays is Improved

The methods of measuring the powerful Lenard or electron rays have been perfected by an investigation of Dr Lauriston S Taylor, of the United States Bureau of Standards

Lenard rays are obtained by pushing electrons through a vacuum tube under a pressure of several hundred thousand volts. By use of a small window of metal or glass the speeding electrons can be obtained in the air outside of the tube. As they have been used, since their first production in large quantities by Dr W D Coolidge, for a great variety of chemical and biological purposes it is important to have an accurate method of measuring them.

Three methods of measuring the rays were compared. Of these the use of a "Faraday

chamber" was found to be most effective. This consists of two metal chambers enclosed one within the other and having openings through which the electrons may pass to the inner chamber.

The alternative methods are by means of an open plate or by means of a condenser. The open plate results were too low, but always in a constant ratio to the Faraday chamber measurements. The condenser method gave results that did not agree with the Faraday chamber results.

The difficulty of making this measurement lies in the fact that the swift electrons striking a metal surface set free other electrons so that the total amount of electricity cannot easily be obtained.—*Science Service*

THE RADIUM TREATMENT OF TOXIC TYPES OF GOITER¹

By D T QUIGLEY, M.D., F.A.C.S., OMAHA, NEBRASKA

THE difference between the types of goiter amenable to radiation treatment and all other types lies in the fact that those in which radiation has proven to be of value are the types accompanied by an increased functional cell activity. In most of these cases there is also a proliferation of cells. Therefore, the problem presented is the problem of reducing the amount of secreting epithelial surface, whether it be contained in an adenoma or in a thyroid hyperplasia. We have also the problem of reducing the degree of hyperactivity of individual cells.

There is an optimum point in thyroid secretion. Departure from this point, either upward or downward, leads to disease. While a small increase in thyroid secretion heightens all the vital powers and functions, a greater degree of increase has a profoundly poisonous effect on all body structures, these effects being particularly noticeable in the nervous system, the brain, and the glands of internal secretion.

In dealing with hypothyroidism or hyperthyroidism, we are dealing simply with a departure from normal quantity in the secretion of the thyroid, the departure being either a lack of the necessary secretion, or an over-supply of the same secretion.

In dealing with adenoma of the thyroid, we have introduced into the equation quite a different factor. We have here to deal with an increased activity of thyroid tissue, but the thyroid tissue in question is not normal. It is a more or less abnormal structure growing inside of a capsule, which in turn, is inside of a thyroid gland. The tumor tissue produces a secretion which is incomplete, or otherwise abnormal in its

manufacture. To a certain degree, it imitates normal thyroid secretion, but it exerts a more poisonous effect owing to the fact that it is not only excessive in amount, but it is also abnormal in chemical make-up. We have here to deal with a question of quality as well as quantity.

In dealing with toxic thyroid, we are dealing with both increased proliferation of cells and increased activity of these cells. Such physiologic behavior suggests an irritating factor in the etiology of the disease, the search for which has been going on for many years. The knowledge now at hand, the most reasonable working hypothesis, is that micro-organisms brought into the gland through the blood, or lymph vessels, and acting directly on the thyroid epithelium are the principal etiologic factors. It is possible that the overgrowth of thyroid tissue may, in some degree, be compensatory. Thyroid secretion combats toxins and infections. An abnormally high amount of material, emanating from foci of low-grade infection, may call out an extra effort on the part of the thyroid infection-fighting mechanism and this, in order to protect the body as a whole, may lead to the overgrowth of the secreting epithelium which has this protective effect. If this theory is correct, then radiation is the treatment of choice because it has the effect of inhibiting or, in larger doses, actually killing the hyperactive and hyperproliferating cells, and also of killing certain low-grade infections. Except in extreme cases, surgical removal of the offending exophthalmic goiter would then be contra-indicated. On this same theory, the surgical removal of thyroid adenoma would be indicated owing to the fact that the secretion here is poisonous, even in small amounts.

¹Read before the Radiological Society of North America at the Seventeenth Annual Meeting at St Louis, Missouri Nov 30-Dec. 4 1931

A factor which must be considered in all goiter work is iodine supply. The secretion elaborated by the thyroid contains iodine. In the absence of sufficient quantities of iodine, the thyroid enlarges in order that a greater number of cells may be put to work to recover iodine from the circulating blood.

The relation between iodine content in food and goiter is well known. The countries in which the soil, and, therefore, the vegetables, are deficient in iodine always carry a high goiter incidence. Those in which iodine is plentiful have relatively few cases of goiter. An example of the latter is the State of South Carolina, which has the highest iodine content in the soil and, therefore, the highest iodine content in the vegetables produced. This State has the lowest goiter incidence.

Goiter is common in valleys which receive little sunshine, such as the narrow valleys in the Swiss Alps. The same thing is true of the mountain valleys in Montana and Wyoming.

Districts in which cistern water is used, instead of well water, have a high goiter incidence. Cistern water contains large numbers of colon bacilli from the deposits made by birds on the roofs of houses. On the prairies of the Dakotas, Minnesota, Michigan, and Wisconsin, we find abundant sunshine, but a deficiency in iodine. These areas produce many cases of goiter. But the goiter incidence is markedly increased here in the districts in which cistern water is used, for, in addition to the patient's experiencing iodine starvation, the upper part of the alimentary canal is exposed to colon bacilli.

We find, then, three factors contributing directly to goiter incidence: (1) iodine starvation, (2) lowered resistance to infections in general on account of deficiencies in food and sunshine, (3) exposure of the upper part of the alimentary tract to water containing colon bacilli.

The toxic types of goiter are, undoubtedly, more common than is generally supposed. Many of these present no tumor mass and are due to an excessive activity, or some little tumor mass is present, but is concealed in the upper part of the chest or behind the sternum. In over-fat persons, it is very easy to fail to discover enlargements, even of normally placed thyroids. These may be located, however, by means of the X-ray.

Toxic conditions of the thyroid are usually accompanied by a high degree of irritability of the nervous system. The patient is nervous, his hands are shaky, and, while he eats large quantities of food, his muscular strength is decreased. His eyes may or may not become more prominent and he may exhibit many symptoms which border on insanity. The whole symptom complex goes through periods of exacerbation followed by periods of quiescence. Each flare-up of symptoms, however, usually becomes a little more severe than the one preceding it. In the later stages of the disease there are no remissions and the symptom complex constantly increases in severity, until death by heart failure occurs.

The action on the heart is, perhaps, the most important effect produced by toxic goiter. It is well known that, in the mortality records, heart disease leads all others by a good margin as a cause of death. It is problematical how much of this mortality may truthfully be attributed to disturbances of the thyroid gland. There is no question but that many diseases diagnosed by physicians as various forms of primary heart disease are, in reality, secondary effects upon the heart produced by thyroid disease. A more general use of basal metabolism tests would uncover the truth in a large number of these cases; however, basal metabolism tests will not completely clear the situation. X-ray films to discover hidden goiters, a more careful examination of patients, and better co-ordination of symptoms and signs

THE RADIUM TREATMENT OF TOXIC TYPES OF GOITER¹

By D T QUIGLEY, M D, F A C S, OMAHA, NEBRASKA

THE difference between the types of goiter amenable to radiation treatment and all other types lies in the fact that those in which radiation has proven to be of value are the types accompanied by an increased functional cell activity. In most of these cases there is also a proliferation of cells. Therefore, the problem presented is the problem of reducing the amount of secreting epithelial surface, whether it be contained in an adenoma or in a thyroid hyperplasia. We have also the problem of reducing the degree of hyperactivity of individual cells.

There is an optimum point in thyroid secretion. Departure from this point, either upward or downward, leads to disease. While a small increase in thyroid secretion heightens all the vital powers and functions, a greater degree of increase has a profoundly poisonous effect on all body structures, these effects being particularly noticeable in the nervous system, the brain, and the glands of internal secretion.

In dealing with hypothyroidism or hyperthyroidism, we are dealing simply with a departure from normal quantity in the secretion of the thyroid, the departure being either a lack of the necessary secretion, or an over-supply of the same secretion.

In dealing with adenoma of the thyroid, we have introduced into the equation quite a different factor. We have here to deal with an increased activity of thyroid tissue, but the thyroid tissue in question is not normal. It is a more or less abnormal structure growing inside of a capsule, which, in turn, is inside of a thyroid gland. The tumor tissue produces a secretion which is incomplete, or otherwise abnormal in its

manufacture. To a certain degree, it imitates normal thyroid secretion, but it exerts a more poisonous effect owing to the fact that it is not only excessive in amount, but it is also abnormal in chemical make-up. We have here to deal with a question of quality as well as quantity.

In dealing with toxic thyroid, we are dealing with both increased proliferation of cells and increased activity of these cells. Such physiologic behavior suggests an irritating factor in the etiology of the disease, the search for which has been going on for many years. The knowledge now at hand, the most reasonable working hypothesis, is that micro-organisms brought into the gland through the blood, or lymph vessels, and acting directly on the thyroid epithelium are the principal etiologic factors. It is possible that the overgrowth of thyroid tissue may, in some degree, be compensatory. Thyroid secretion combats toxins and infections. An abnormally high amount of material, emanating from foci of low-grade infection, may call out an extra effort on the part of the thyroid infection-fighting mechanism and this, in order to protect the body as a whole, may lead to the overgrowth of the secreting epithelium which has this protective effect. If this theory is correct, then radiation is the treatment of choice because it has the effect of inhibiting, or, in larger doses, actually killing the hyperactive and hyperproliferating cells, and also of killing certain low-grade infections. On this same theory, the surgical removal of thyroid adenoma would be indicated owing to the fact that the secretion here is poisonous, even in small amounts.

¹Read before the Radiological Society of North America at the Seventeenth Annual Meeting at St Louis Missouri, Nov 30-Dec 4 1931

A factor which must be considered in all goiter work is iodine supply. The secretion elaborated by the thyroid contains iodine. In the absence of sufficient quantities of iodine, the thyroid enlarges in order that a greater number of cells may be put to work to recover iodine from the circulating blood.

The relation between iodine content in food and goiter is well known. The countries in which the soil, and, therefore, the vegetables, are deficient in iodine always carry a high goiter incidence. Those in which iodine is plentiful have relatively few cases of goiter. An example of the latter is the State of South Carolina, which has the highest iodine content in the soil and, therefore, the highest iodine content in the vegetables produced. This State has the lowest goiter incidence.

Goiter is common in valleys which receive little sunshine, such as the narrow valleys in the Swiss Alps. The same thing is true of the mountain valleys in Montana and Wyoming.

Districts in which cistern water is used, instead of well water, have a high goiter incidence. Cistern water contains large numbers of colon bacilli from the deposits made by birds on the roofs of houses. On the prairies of the Dakotas, Minnesota, Michigan, and Wisconsin, we find abundant sunshine, but a deficiency in iodine. These areas produce many cases of goiter. But the goiter incidence is markedly increased here in the districts in which cistern water is used, for, in addition to the patient's experiencing iodine starvation, the upper part of the alimentary canal is exposed to colon bacilli.

We find, then, three factors contributing directly to goiter incidence: (1) iodine starvation, (2) lowered resistance to infections in general on account of deficiencies in food and sunshine, (3) exposure of the upper part of the alimentary tract to water containing colon bacilli.

The toxic types of goiter are, undoubtedly, more common than is generally supposed. Many of these present no tumor mass and are due to an excessive activity, or some little tumor mass is present, but is concealed in the upper part of the chest or behind the sternum. In over-fat persons, it is very easy to fail to discover enlargements, even of normally placed thyroids. These may be located, however, by means of the X-ray.

Toxic conditions of the thyroid are usually accompanied by a high degree of irritability of the nervous system. The patient is nervous, his hands are shaky, and, while he eats large quantities of food, his muscular strength is decreased. His eyes may or may not become more prominent and he may exhibit many symptoms which border on insanity. The whole symptom complex goes through periods of exacerbation followed by periods of quiescence. Each flare-up of symptoms, however, usually becomes a little more severe than the one preceding it. In the later stages of the disease there are no remissions and the symptom complex constantly increases in severity, until death by heart failure occurs.

The action on the heart is, perhaps, the most important effect produced by toxic goiter. It is well known that, in the mortality records, heart disease leads all others by a good margin as a cause of death. It is problematic how much of this mortality may truthfully be attributed to disturbances of the thyroid gland. There is no question but that many diseases diagnosed by physicians as various forms of primary heart disease are, in reality, secondary effects upon the heart produced by thyroid disease. A more general use of basal metabolism tests would uncover the truth in a large number of these cases; however, basal metabolism tests will not completely clear the situation. X-ray films to discover hidden goiters, a more careful examination of patients, and better co-ordination of symptoms and signs

must be the rule if the thyroid hearts are to be separated from other forms of heart disease. If the large number of thyroid hearts which operate as causes of death are removed from the list of heart diseases and placed in the category of thyroid disease, where they belong, not only would the mortality records show an improvement in the situation as regards heart disease, but also many cures might be effected in these cases of thyroid disease. Thus the mortality records in both heart and thyroid diseases might be very much bettered.

In exophthalmic goiter, the ideal therapy is that which directly reduces the number of proliferating secreting cells and reduces the activity of the cells which remain. If this therapy also carries a direct killing effect on low-grade micro-organisms, then it leaves little to be desired except the clearing out of foci of infection which may be feeding micro-organisms into the diseased thyroid.

In the surgical treatment of the disease, nothing is accomplished except the mechanical removal of the over-secreting and hyperplastic mass of cells. The area of thyroid tissue which remains after a surgical operation is likely to go through the same kind of hyperplasia again, because the cause of the disease has not been removed. Clinically, the truth of this is shown far too often and we occasionally see cases in which exophthalmic goiter has recurred many times.

CASE REPORTS

In 1916, the author treated his first patient with radium—a woman who had already submitted to three operations for recurring exophthalmic goiter. Following the last operation, the goiter had, in a period of three months, recurred to its original size and severity. A dose of 150 mg was administered over the enlarged thyroid in three 3-hour treatments, the treated area be-

ing changed so that the whole area was evenly irradiated. After waiting a period of three months, in which time the patient showed definite signs of improvement, the treatment was repeated. It was again repeated after another three-months period. The size of the enlarged gland was very materially reduced, the symptoms disappeared, the prominent eyes became somewhat less prominent and, since the time that this treatment was given, the patient has been well.

During the same year, a patient was treated who was considered to be in a dying condition from heart disease. She was 24 years of age and had a history of having been ill with heart symptoms, rapid pulse, and muscular weakness for several months. She had been confined to bed for four and a half months. She had consumed quantities of digitalis and other heart medicines. The woman was very much emaciated, exceedingly nervous, and mentally in a condition approaching mania. As she lay in bed, it was noticed that she had a rather prominent swelling in the region of her thyroid and I suggested the application of 60 mg of radium heavily screened over the swollen thyroid. The application was made for a period of 13 hours. Three weeks later the patient was much improved. Her pulse, which had been so rapid that it could not be counted, had come down to 120. Her muscular strength was so much better that she sat up in bed. Her mental condition was clearer. At this time another application of 60 mg of radium was applied for 13 hours. Three weeks after the second application the patient was able to be up in a chair, and from that time on her progress was continuous. After three months, she was given another treatment. At this time she expressed a desire to resume her occupation as school teacher, but she was advised to rest for one year. During this year she was married. Now, 15 years have

elapsed since her treatment. During these years she has had no recurrence, although she has experienced very severe mental strain. Her husband, a banker, was imprisoned for two years following the failure of his bank. The patient went through these periods of strains and stresses and is now back at her old occupation, teaching school, without any recurrence of her hyperthyroid symptoms.

In 1917, during the war hysteria, a farmer's wife presented herself with all the symptoms of an advanced exophthalmic goiter. Her troubles were accentuated by war conditions. She was obliged to take care of five small children, the animals about the farm, do the milking, the churning, and other necessary duties. Her position was almost intolerable. She was kept in the hospital three days and 120 mg of radium applied separately over each lobe of the thyroid and the isthmus. She was instructed to rest three months, no matter what the cost might be, as her weakened heart could not possibly withstand a continuation of the strains to which it had been subjected. Four months later she returned, apparently well, and having gained several pounds in weight. I suggested to her that the rest had probably been the principal factor in her recovery. She replied that she had taken no rest, and, not having been able to secure help for either the farm or the house, had carried on her work exactly as before her treatment. The improved condition could be attributed to nothing but the radium treatment. As there were some nervous symptoms and rapidity of pulse still apparent, she was given another treatment, remaining in the hospital a day and a half. We did not see this patient again until four years later, when she came to the city. As she had remained well, no other treatment was used except the removal of two crowned dead teeth which we presumed might have had some etiologic relationship to the goiter.

In 1918, a woman, 45 years of age, came from a small town in South Dakota where cistern water was used for drinking purposes. The well water in this neighborhood was contaminated with more or less iron which gave it a bitter taste, and, on drying, produced a red precipitate. This sediment convinced the inhabitants that the well water was unwholesome. The woman had a moderately enlarged thyroid gland with all the signs and symptoms of exophthalmic goiter. Her thyroid was irradiated and an infected maxillary sinus drained. This, with a three-day stay in the hospital, started her on the road to recovery and in three months her symptoms were entirely cleared up. She has remained well since then. She was instructed to discontinue the use of cistern water.

In the latter part of October, 1920, a post-office employee, 40 years of age, was referred by an Omaha physician for treatment for exophthalmic goiter. The thyroid was very much enlarged, presenting a mass like a collar encircling both sides and the front of his neck. His pulse was 140. He had applied for relief to his physician, because he had found that his muscular strength was failing to such an extent that he could hardly continue with his work—loading heavy mail sacks on to trucks. This patient was extremely nervous and shaky. Owing to the fact that he had a large family and a small income, he felt that he could not afford to give up his work and enter the hospital for an operation. He was given a radium treatment which consisted of the application of 120 mg of radium, screened with 1 mm of silver and 1 mm of brass at a distance of 2 cm, for 20 hours over each lobe and for the same length of time over the isthmus. After six weeks this was repeated, but with half the amount of radium used in the first treatment. The patient who kept on with his work received no other treatment except that two

badly diseased teeth were removed. During the months of November and December, his work increased very materially on account of the Christmas rush, but during this time he was able to continue without intermission. It was felt at the time that the situation, putting an extra strain on his heart muscle as it did, would lead to a permanently damaged heart, however, nothing of this kind has developed. The patient has kept on at the same work during the 11 years intervening and at the present time is apparently well.

In my experience, favorable results, which may be comparable with results obtained by surgical operation have been obtained in approximately 70 per cent of the cases treated. We have found that the cases which do not respond well to treatment by surgical operation and that recur after surgical operation usually respond well to radium radiation. On the other hand, cases which fail to show good results following radium treatment are usually good cases for surgery. I do not know of a case that has been properly treated with radium radiation, even though the radium radiation has been unsuccessful in controlling the symptoms, that has recurred following a subsequent surgical operation. Apparently the radium radiation reduces the likelihood of recurrence, or prevents it altogether. Radium treatment, then, helps to make surgery more efficient in this particular class of cases. In those unsuccessfully treated cases that have been followed to the operating room, there has been no increase in the difficulties incident to the removal of the goiter. No adhesions have been noticed in any case, but in many of the diseased glands that have been subjected to radium treatment an increased hardness has been noticed, due to the production of considerable amounts of connective tissue. The firmness and hardness which occur in some of these irradiated glands probably make it easier for the

surgeon to remove the diseased tissue, because it does not collapse under his fingers like ordinary thyroid tissue.

During the period between 1915 and 1927 we have treated 137 cases. No account is taken of cases since 1927, as we believe that sufficient time has not elapsed in the latter to justify recording the results at this time. This group contains 18 patients treated as charity patients and in the University Hospital and 119 treated in private practice. Of the University Hospital and charity patients, 12 were subsequently recommended for surgical operation. Only five responded successfully to the radium treatment. One left the hospital without completing the treatment. Of the cases treated in private practice during the same time period, 83 were sufficiently improved so that subsequent surgical intervention has not been necessary, 35 have shown little or no improvement and have been referred for surgery. Some of these patients have since died from other diseases, some have been lost, and some have had satisfactory results from surgical operations. In the cases successfully treated with radium are 15 who had previously been operated upon, but in whom there had been one or more recurrences.

It will be noted that, in the University Hospital and charity patients, the percentage of satisfactory results was much less than among private patients. This may be accounted for by the fact that the University Hospital patients are generally paupers, poorly fed and poorly housed, it being impossible for them to secure good living conditions after they have left the hospital. The private patients, on the other hand, were well fed, well housed, and did not have to suffer from the mental stresses and strains incident to pauperism, on leaving the hospital, they went back to good homes and good food.

In the cases that show satisfactory results after radium treatment, the first symptoms

to show improvement are those of nervous origin. The patient's extreme nervous irritability becomes markedly lessened, usually within the first three days. Muscular strength is noticeably increased within the first week. Mental excitability is much improved after the first five or six days. The patient who has been on the verge of mania will appear calm and placid after two or three weeks. There is usually considerable reduction in the size of the thyroid gland. In some cases the gland has been reduced apparently to normal size. In many, the reduction in size is only partial. This, of course, is not satisfactory to the patient who wishes all objective evidences of the disease removed. The same thing may be said about the undue prominence of the eyes. In some cases, the eyes recover the normal appearance. Most maintain a certain degree of prominence of the eyes even after all other signs and symptoms of the disease have disappeared. Usually, however, it is lessened, but not completely reduced to normal. The diarrhea which accompanies some cases of goiter is usually improved early and the patient's ability to digest food is better. These patients are nearly all below normal weight. With an increased ability to digest food and a lessened oxidation the weight increases. In no cases have I seen myxedema follow radium treatment. Apparently complete destruction of thyroid tissue is not possible with radium as long as the metal screening and the distance are correctly estimated and the dose is kept within reasonable limits.

In regard to toxic adenoma, the results with radium have not been so satisfactory as with exophthalmic goiter. The percentage of cases requiring subsequent operation is approximately 50. The cases of adenoma that respond show the beneficial effect very quickly, so that, if it is desired to use the therapeutic test on such a patient, ten days or two weeks will show whether it is better

treated by radium radiation or surgery. In such cases, no skin burn which might interfere with surgical operation need be produced.

It is probable that in some cases there also exists, in some degree, coincident disease involving the parathyroids. In no case in our group has any injurious action on the parathyroids been noted. This fact should be considered in connection with the possibility of accidental removal of the parathyroid, which sometimes occurs during surgical operation.

The destructive action of radium radiation on the diseased tissues seems to be present in both toxic adenoma and exophthalmic goiter. The percentage of actual cures is much higher in exophthalmic goiter because here we are simply inhibiting excessive activity. In adenomas, the actual destruction of tumor tissue by the radiation is necessary. In both adenomatous and exophthalmic goiter cases we occasionally perceive unusual symptoms which seem to indicate that both hypothyroidism and hyperthyroidism are present. Even in these cases the radium radiation seems to help to restore normal balance. This is probably due to the fact that the radiation kills low-grade infecting organisms of different types, some of which are stimulating and some of which are inhibiting to the particular epithelium in which they happen to lodge. Thyroid secretion is, undoubtedly, a complex product that may carry simultaneously certain potent elements in hyper- and others in hypo-quantities.

Some cases of exophthalmic goiter are accompanied by persistent thymus. In these it is necessary to irradiate the thymus as well as the thyroid. Care must be taken not to mistake a persistent thymus for a substernal goiter. Here a therapeutic test may make clear the diagnosis, as a thymus always shrinks very quickly after radiation,

badly diseased teeth were removed. During the months of November and December, his work increased very materially on account of the Christmas rush, but during this time he was able to continue without intermission. It was felt at the time that the situation, putting an extra strain on his heart muscle as it did, would lead to a permanently damaged heart, however, nothing of this kind has developed. The patient has kept on at the same work during the 11 years intervening and at the present time is apparently well.

In my experience, favorable results which may be comparable with results obtained by surgical operation, have been obtained in approximately 70 per cent of the cases treated. We have found that the cases which do not respond well to treatment by surgical operation and that recur after surgical operation usually respond well to radium radiation. On the other hand, cases which fail to show good results following radium treatment are usually good cases for surgery. I do not know of a case that has been properly treated with radium radiation, even though the radium radiation has been unsuccessful in controlling the symptoms, that has recurred following a subsequent surgical operation. Apparently the radium radiation reduces the likelihood of recurrence, or prevents it altogether. Radium treatment, then, helps to make surgery more efficient in this particular class of cases. In those unsuccessfully treated cases that have been followed to the operating room, there has been no increase in the difficulties incident to the removal of the goiter. No adhesions have been noticed in any case, but in many of the diseased glands that have been subjected to radium treatment an increased hardness has been noticed, due to the production of considerable amounts of connective tissue. The firmness and hardness which occur in some of these irradiated glands probably make it easier for the

surgeon to remove the diseased tissue, because it does not collapse under his fingers like ordinary thyroid tissue.

During the period between 1915 and 1927 we have treated 137 cases. No account is taken of cases since 1927, as we believe that sufficient time has not elapsed in the latter to justify recording the results at this time. This group contains 18 patients treated as charity patients and in the University Hospital and 119 treated in private practice. Of the University Hospital and charity patients, 12 were subsequently recommended for surgical operation. Only five responded successfully to the radium treatment. Of the cases treated in private practice during the same time period, 83 were sufficiently improved so that subsequent surgical intervention has not been necessary, 35 have shown little or no improvement and have been referred for surgery. Some of these patients have since died from other diseases, some have been lost, and some have had satisfactory results from surgical operations. In the cases successfully treated with radium are 15 who had previously been operated upon, but in whom there had been one or more recurrences.

It will be noted that, in the University Hospital and charity patients, the percentage of satisfactory results was much less than among private patients. This may be accounted for by the fact that the University Hospital patients are generally paupers, poorly fed and poorly housed, it being impossible for them to secure good living conditions after they have left the hospital. The private patients, on the other hand, were well fed, well housed, and did not have to suffer from the mental stresses and strains incident to pauperism, on leaving the hospital, they went back to good homes and good food.

In the cases that show satisfactory results after radium treatment, the first symptoms

THE PREVENTION OF HYPERPLASIA OF THE THYROID IN THE OPOSSUM BY X-RAYS¹

By O M WALTER, M D, B J ANSON, PH D, and A C IVY, PH D, M D,
From the Departments of Physiology and Anatomy, Northwestern University Medical School,
CHICAGO, ILLINOIS

THE experimental literature, which we reviewed in a previous article (1), shows that *normal* thyroid tissue is resistant to X-rays. The clinical literature reveals practically nothing concerning the effect of X-rays on the hyperplastic gland but does indicate that X-ray treatment benefits, at least temporarily, some 60 per cent of patients afflicted with hyperthyroidism. No observations have been made to ascertain if X-rays may prevent hyperplasia.

Bensley (2) has shown that, if opossums, when confined to cages, are fed a high protein meat diet, the thyroid undergoes marked hyperplasia which is quite evident in two weeks. He could not prevent this hyperplasia with iodine, but it did cause the hyperplastic gland to store colloid. Hence, we had at hand a method for determining if X-rays may prevent hyperplasia of the thyroid.

METHODS

Dosage—The same dosage used in our previous study (1), which was used by B H Orndoff, for the treatment of hyperthyroidism, was employed. For our equipment the factors were as follows: ma, 4, sphere gap, 130, peak, 177, filter, 0.25 mm Cu plus 1 mm Al, portal, 5×8 cm, distance, 50 cm, time, 55 min, yielding 385 r units. One series consisted of one dose given at weekly intervals for four weeks (four doses). A month was allowed to elapse before a second series was given.

Experiments—Sixteen opossums were obtained from Texas. One was killed on the day of arrival and the thyroid which was removed, weighed, and examined his-

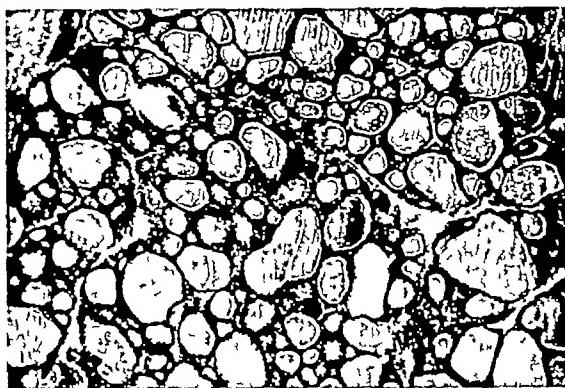

Fig 1 Normal thyroid of opossum on receipt at the laboratory and before meat diet. Magnification 60 times

tologically was found to be normal. Eight were treated with X-ray, seven being used as controls. Three of the eight (Lot 1) treated were started on meat and X-ray treatment at the same time. The other five (Lot 2) were started on meat immediately after the conclusion of the first series.

RESULTS

Since Bensley found that the thyroids were normal on receipt of the opossums and remained so when the animals were kept on a proper diet, we sacrificed only one of our opossums to determine the state of the thyroid on coming into the laboratory. It was found to be normal and a section of it is shown in Figure 1. The average weight of the glands of nine opossums, found by Bensley to be histologically normal, was 157 milligrams.

Lot 1—In this lot, X-ray treatment was started at the same time as the meat diet. A study of Table I shows that the glands of the controls, the animals that received meat but no X-ray treatment, were markedly hyperplastic. Follicles were rare. The measurements show that the glands were

¹Read before the Radiological Society of North America
at the Seventeenth Annual Meeting, at St Louis Nov 30-Dec 4 1931

while the substernal goiter requires operation. Patients with persistent thymus invariably present an unnaturally youthful appearance, seeming to be from 10 to 15 years younger than their real age.

In this series of cases we have included no cancers or other neoplasms of the thyroid—except toxic adenoma—no cysts, anomalies, or any of the various kinds of thyroiditis.

Patients who have made a successful recovery from goiter must be careful that a relapse does not occur no matter what form of treatment may have been used. Not only

must all foci of infection be eliminated, but other hygienic measures must be considered so that the general resistance to infection is kept at the highest possible point. Food must be considered from the standpoint of calcium, iron, iodine, and vitamin content. Starvation for any particular vitamin of the protective group, A, B, and C, is very likely so to reduce the whole infection-fighting mechanism of the body as to render the patient the victim of deficiency diseases which invite infections and may thereby help to reproduce the original thyroid disease.

Fourteen Points Govern Building of Atom Cores—Fourteen points for the government of the atom nucleus have been formulated by Prof W D Harkins, University of Chicago.

Physicists will be aided in their search for the secret of the atom nucleus by these rules. The stability and formation of the ninety-two elements of the chemist's periodic table of atoms are intimately governed by them. They relate particularly to the atomic weight and the atomic number, or order number of the element in the table.

Nature is most often even in making her atom cores, Professor Harkins finds. Nearly all atomic nuclei contain an even number of electrons. The atomic number and the number of protons in the nucleus are generally even, too.

Elements of even atomic number, the newest data indicate, are ten times more abundant on the surface of the earth or on the sun. In meteorites the atom nuclei of elements of even atomic number are fifty times more abundant.

TABLE I (LOT 1)

| Serial number | Disposal of animals | Measurement of glands (millimeters) | | | Dosage (series) | Diet-period | Histologic condition | Histologic observations |
|---------------|---------------------|-------------------------------------|---------|-------|-----------------|-------------|------------------------------|---|
| | | Length | Breadth | Depth | | | | |
| Controls | | | | | | | | |
| 1 | Fresh P M | 20 | 4.5 | | | 3/1-7/26 | Fair Epithelial desquamation | Hyperplastic * Follicles rare and small |
| 2 | Killed | 24 | 10 | — | | 3/1-8/4 | Similar to No 1 | Hyperplastic More vascular than No 1 |
| 3 | 2 hrs P M | 18 | 9 | 8 | | 3/1-8/8 | Poor | Hyperplastic Few follicles present Vessels engorged |
| 4 | Killed | 16 | 7 | 8 | | 3/1-10/6 | Good | Markedly hyperplastic Small follicles common (Like No 13, Lot 2) One gland very vascular General picture cord-like masses or small follicles pressed upon by engorged capillaries |
| Treated | | | | | | | | |
| 24 | Killed | 13 | 5 | — | 3 | 5/1-10/6 | Good | Hyperplastic, but small follicles numerous, few large (similar to No 61 of Lot 2) |
| 51 | 12 hrs P M | 7 | 4.5 | — | 1½ | 3/1-6/6 | Poor | Somewhat follicular |
| 55 | Killed | 13 | 7.5 | 4 | 2 | 3/1-7/13 | Good | Hyperplastic, but small follicles fairly numerous (similar to No 24, above, and also to No 61 of Lot 2) |

* The hyperplastic thyroid gland presents in sections a "hugely cellular," as opposed to a "follicular," appearance. The colloid filled follicles of the normal gland tend generally to be replaced by masses of cells which may assume a cord-like arrangement. Such smaller follicles as remain contain little or no colloid and hence reduced lumens bounded by epithelial cells which show a distinct increase in size over that of the cells in an unaltered gland.

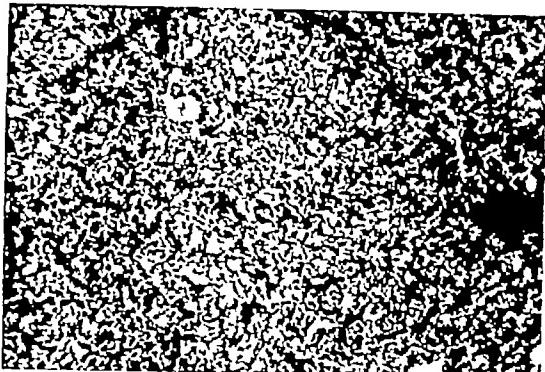

Fig 2 Hyperplasia of thyroid of opossum (13) induced by a meat diet, serving as a control to the X-ray treated thyroid in Figure 3. Magnification 60 times

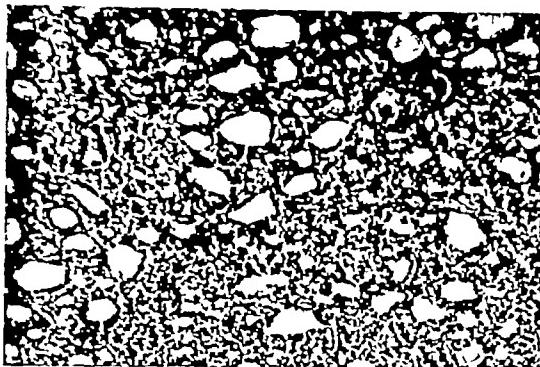

Fig 3 Showing the thyroid of an opossum (65) on meat diet that received two series of X-ray treatments. Hyperplasia has occurred but not to the extent of the controls on meat diet without X-ray. Magnification 60 times

grossly enlarged, while the glands of the animals that received X-ray treatment were hyperplastic, but contained numerous small follicles. The measurements of the glands show that they were smaller than the controls.

Lot 2—In this lot the meat diet was not started until after the first series of X-ray treatments. In general the results are the same as those obtained in Lot 1. The difference in the measurements of the treated and untreated glands corresponds with the weights (Table I). It is to be noted that the average weight of the untreated glands was 404 and of the treated 294 milligrams. Although the treated glands of Opossums 62 and 63 weighed as much as the untreated

the histologic picture was quite different (Figs 1 and 2)

Epilation of the hair of the neck occurred in all opossums which received two or more series

These results show that X-rays in the dosages used prevent, to a considerable extent, the hyperplasia of the thyroid gland of the opossum induced by a diet rich in meat. It is possible that, had we reduced the amount of meat fed and used larger doses of X-rays, the hyperplasia might have been entirely prevented. However, we suspect that, if we had done this, our results would have been more variable and difficult to interpret.

These results support the clinical effectiveness of X-ray treatment of the thyroid gland in some cases of hyperthyroidism and indicate that the reason for failure in others is due to an insufficient amount of X-ray treatment to combat the marked tendency to hyperplasia in these particular cases. Our results suggest the possibility that X-ray treatment may be of benefit in preventing recurrences following subtotal thyroidectomy and that X-ray treatment may be a valuable adjunct to iodine medication in bringing about involution.

This work is now being continued on rabbits in which thyroid hyperplasia can be induced by feeding cabbage (3) and in which metabolic studies can be readily made.

CONCLUSION

The hyperplasia of the thyroid gland that occurs in opossums on a high protein (meat) diet was definitely decreased, but not entirely prevented, by the X-ray dosages employed.

DISCUSSION

DR. W H OLMSTED (St Louis, Mo) On the one hand, we have the fact that the surgeons have obtained very excellent results from thyroidectomy and, on the other hand, the radiologists have as good results from roentgen therapy. The physician is at a loss to know which of these two therapeutic agents to use in the individual case he may be called upon to treat.

What are the indications for surgery and what are the indications for roentgen treatment? My experience has not been broad, so I cannot present to you hundreds of cases. Three years ago I began to treat a few cases of hyperthyroidism with X-rays, in association with Dr Sherwood Moore, however, I cannot give you Dr Moore's technic.

Some of the facts that our experience has taught us are as follows:

One treatment will reduce, on an average, the basal metabolic rate 10 per cent. It is, therefore, apparent that, with the technic we have been using, the patient with a very high metabolic rate would require six, or more, roentgen treatments. It is our belief that deep therapy should not be given more often than once every six weeks because of the danger of burns. If this be the case, it is apparent that to treat a thyroid patient with a very high rate requires a great deal of time. If he is to have six treatments, it will require 36 weeks to give the treatments. For these reasons we believe that roentgen treatment is adaptable only to those cases which show an increase in their basal rates of not more than 40 per cent. In such patients, one can safely delay treatment. It is also the best therapy in the mild case of hyperthyroidism, because there is less likelihood of a resulting myxedema when one uses the X-rays than when the surgeon is compelled to judge how much thyroid to remove.

A further group in which roentgen treatment of hyperthyroidism has been of particular use is that in which there are complications by other diseases such as diabetes, arteriosclerosis, and heart disease. In this group, we believe that roentgen therapy is of less risk than operation. However I had one case, an old man who had had one stroke of apoplexy,

presenting hyperthyroidism. He was given one roentgen treatment and died during the night following the treatment. I cite this case to show that roentgen treatment is not without some danger.

In conclusion, it seems to me that there is a place for roentgen therapy in the milder types of hyperthyroid cases, especially in those which are complicated by the presence of diabetes, heart disease, or arteriosclerosis. Those cases which are more severe, with high metabolic rates, should have operation. In them, the danger of post-operative myxedema is very slight, whereas, in the milder cases, myxedema is apt to occur. There is a more definite tendency of the return of an elevation of the basal metabolic rate after roentgen therapy than after operation. One cannot emphasize enough the point that Dr Bartlett has brought out the necessity of following cases of hyperthyroidism for months, or years, after the treatment has been begun.

DR O P J FALK (St Louis, Mo) We have heard the radiologist state the mistakes the surgeon probably has made, and we have heard the surgeon state his position. It might not be amiss for us to enumerate a few ways in which we internists make mistakes.

In simple goiters with adenomas, the prolonged use of iodine may precipitate hyperthyroidism. A previously impalpable adenoma may become distinguishable, which, when the symptoms do not subside, often requires surgery. Boothby advises against the use of iodine, except pre-operatively, in all patients over 25 years of age. Morine states that all reactions may be avoided by the use of a maximum of 10 mg daily for not over one month, or not more than 1 mg daily continuously. When we realize that one drop of Lugol's solution contains 8.5 mg of iodine, we readily appreciate how often this limit of safety is exceeded (one minim of syrup ferrans iodide contains 3 mg of iodine).

Another medical error is failure to recognize the syndrome Lahey terms "apathetic type of hyperthyroidism." This comes on in middle or later life, lacks typical clinical signs, and is often characterized only by an unex-

TABLE I (LOT 2)

DISCUSSION

DR W H OLMIESTED (St Louis, Mo) On the one hand, we have the fact that the surgeons have obtained very excellent results from thyroidectomy and, on the other hand, the radiologists have as good results from roentgen therapy. The physician is at a loss to know which of these two therapeutic agents to use in the individual case he may be called upon to treat.

What are the indications for surgery and what are the indications for roentgen treatment? My experience has not been broad, so I cannot present to you hundreds of cases. Three years ago I began to treat a few cases of hyperthyroidism with X-rays, in association with Dr Sherwood Moore, however, I cannot give you Dr Moore's technic.

Some of the facts that our experience has taught us are as follows:

One treatment will reduce, on an average, the basal metabolic rate 10 per cent. It is, therefore, apparent that, with the technic we have been using, the patient with a very high metabolic rate would require six, or more, roentgen treatments. It is our belief that deep therapy should not be given more often than once every six weeks because of the danger of burns. If this be the case, it is apparent that to treat a thyroid patient with a very high rate requires a great deal of time. If he is to have six treatments, it will require 36 weeks to give the treatments. For these reasons we believe that roentgen treatment is adaptable only to those cases which show an increase in their basal rates of not more than 40 per cent. In such patients, one can safely delay treatment. It is also the best therapy in the mild case of hyperthyroidism, because there is less likelihood of a resulting myxedema when one uses the X-rays than when the surgeon is compelled to judge how much thyroid to remove.

A further group in which roentgen treatment of hyperthyroidism has been of particular use is that in which there are complications by other diseases such as diabetes, arteriosclerosis, and heart disease. In this group, we believe that roentgen therapy is of less risk than operation. However, I had one case, an old man who had had one stroke of apoplexy,

presenting hyperthyroidism. He was given one roentgen treatment and died during the night following the treatment. I cite this case to show that roentgen treatment is not without some danger.

In conclusion, it seems to me that there is a place for roentgen therapy in the milder types of hyperthyroid cases, especially in those which are complicated by the presence of diabetes, heart disease, or arteriosclerosis. Those cases which are more severe, with high metabolic rates, should have operation. In them, the danger of post-operative myxedema is very slight, whereas, in the milder cases, myxedema is apt to occur. There is a more definite tendency of the return of an elevation of the basal metabolic rate after roentgen therapy than after operation. One cannot emphasize enough the point that Dr Bartlett has brought out the necessity of following cases of hyperthyroidism for months, or years, after the treatment has been begun.

DR O P J FALK (St Louis, Mo) We have heard the radiologist state the mistakes the surgeon probably has made, and we have heard the surgeon state his position. It might not be amiss for us to enumerate a few ways in which we internists make mistakes.

In simple goiters with adenomas, the prolonged use of iodine may precipitate hyperthyroidism. A previously impalpable adenoma may become distinguishable, which, when the symptoms do not subside, often requires surgery. Boothby advises against the use of iodine, except pre-operatively, in all patients over 25 years of age. Morine states that all reactions may be avoided by the use of a maximum of 10 mg daily for not over one month, or not more than 1 mg daily continuously. When we realize that one drop of Lugol's solution contains 8.5 mg of iodine, we readily appreciate how often this limit of safety is exceeded (one minim of syrup ferrans iodide contains 3 mg of iodine).

Another medical error is failure to recognize the syndrome Lahey terms "apathetic type of hyperthyroidism." This comes on in middle or later life, lacks typical clinical signs, and is often characterized only by an unex-

TABLE I (LOT 2)

| Serial number | Disposal of animals | Measurement of glands (millimeters) | | | Weight milligrams | Dosage (series) | Diet-period | Histologic condition | Histologic observations |
|----------------|-----------------------|-------------------------------------|---------|-------|-------------------|-----------------|--------------|----------------------|---|
| | | Length | Breadth | Depth | | | | | |
| Controls 11 | Killed day of arrival | 11 | 4 | — | | | Not dictated | Good (Fig 1) | Unaltered follicular structure |
| 10 | Killed | 12.5 | 5 | 3 | 445 | | 1/7-3/12 | Good | Reduced number of follicles, hyperplastic |
| 13 | Killed | 15 | 6 | 4 | 380 | | 1/7-3/19 | Good (Fig 2) | Further reduction in number of follicles, hyperplasia more marked than in No 10 |
| 14 | Killed | 13 | 7 | 4 | | | | | No 10 and No 13 |
| | | 14 | 6 | 4 | 390 | | 1/7-3/19 | Good | Change intermediate between that of No 10 and No 13 |

cide that it is useful as a palliative, as a means which will produce results lasting much longer than three months and possibly over a period of several years, amounting to a cure in a considerable percentage of cases

I have had no experience with injections nor have I been associated with clinics in which injection methods have been employed. I had an experience with one case in which hot water injection had been used, but finally radiation was employed, apparently with good results, lasting something over three years. I do not know whether it was the hot water injection or the roentgen treatment that did the work.

I have never seen a myxedema resulting from irradiation. I had one patient with carcinoma of the thyroid who was referred for roentgen therapy before the wound was healed. A portion of the middle lobe had been removed to take the pressure off the trachea, so that the patient could breathe. She was then referred for roentgen treatment in the hope of accomplishing something. I gave her persistent treatments over 14 months, treating her with a series every three weeks. After this period the patient was apparently cured and I let her go. Now, 16 years have gone by and she is still alive and well. Ever since the basal metabolic method has been introduced I have had her metabolism estimated every year or two. It is approximately normal and has been so ever since we began the estimations. If I ever had a case that ought to have exhibited myxedema, that is the case. I also have a very strong impression, based on experimental work, that we cannot damage a normal thyroid very much by roentgen therapy.

I have had experience with six malignancies of the thyroid, as I remember *et tempore*. Three of these patients are alive.

I think there are certain definite contraindications to radiotherapy. We have mentioned the economic reasons, with which we will all agree, for it is sometimes cheaper to do the operation and get the patient back to earning his livelihood. Second, impending heart damage may indicate immediate surgery. I do not think we are justified in waiting for a temporizing method to stop the damage that

is going on when a surgical operation will stop it very shortly. I do not believe roentgen therapy is indicated when we are dealing with a large toxic thyroid. It is damaging both by size and by toxicity and should be relieved by surgery. I have not had any success in the roentgen treatment of substernal thyroids. Patients with small toxic goiters, not exhibiting serious heart damage, and whose economic situation permits it, are ideal subjects for roentgen therapy.

DR E L JENKINSON (Chicago). Regarding what Dr Richter said about "cure," I have tried to guard against using the word "cure." In most of the papers I have written on the roentgen treatment of thyroid disease I have tried to use "symptom-free," rather than "cure." I think as he does—patients may have the disease though they live fifty years.

I think I would prefer to treat a patient with a high metabolic rate rather than one with a rate of approximately 20. It has been our experience that patients with high metabolic rates have responded better than those with low rates. In older patients our results have not been good, in fact, I had rather not treat them.

Regarding mortality. Eight years ago we reported two deaths. There is no secret about it—these two patients died. They have been reported. To what death was due, I do not know. Following the second series, one patient became bronzed and died.

We have treated over 1,000 patients. Those patients did not come to me directly, but were referred by very competent internists on our staff. If the method had absolutely no virtue, no curative power, I do not think those men would have sent the patients for therapy.

DR WILLARD BARTLETT (closing). I have nothing to add, except that this has been a wonderfully helpful and illuminating session. I value particularly the remarks of Dr Case, because he has been both a radiologist and a surgeon.

DR H M RICHTER (closing). I am afraid that oftentimes men fail to get together in dis-

plained weight loss, tachycardia, and myasthenia

Another mistake is lack of realization of the potential menace, after the fortieth year, of an adenomatous goiter without hyperthyroidism. In these cases, hyperthyroidism frequently develops so insidiously that it may exist for a long time before the patient is aware of any symptoms.

Plummer has recently called attention to the frequency of this fact, as well as to the surprising frequency of malignancy of this gland, the ratio being 27 per cent of all the thyroids removed at the Mayo Clinic. However, we must remember that this proportion exists for the truly pathologic glands actually removed, and not for cases of thyroid adenomas which are asymptomatic, hence untreated.

As to the choice between surgery and the roentgen ray, in the uncomplicated case, the consensus of opinion unquestionably seems to favor removal. Yet we feel that roentgenotherapy has a very definite place in the treatment of cases when surgery is inadvisable or refused.

The treatment of thyrotoxicosis is a problem in which, in any individual case, adherence to fairly well established precedents must be tempered with sound judgment in the choice of procedure. Here again, the patient must be treated, and not the disease alone, for, in hyperthyroidism, the man the disease has is of equal importance with the disease the man has.

Inasmuch as our choice of procedure is necessarily bound to be influenced, to some extent, by our particular field of endeavor, our contacts, and experience, we must constantly keep in mind the limitations, as well as the potentialities, of any particular form of treatment.

The management of every thyrotoxic case is essentially a medical problem, because of the fundamental metabolic upheaval, the cardiovascular involvement, the neuropsychic upset, and the autonomic nervous system imbalance. Nevertheless we must realize, in the majority of severe cases, particularly of the toxic adenomatous type, the inadequacy of

complete ultimate medical control of the situation.

The fundamental principles of medical treatment are recognized to be:

- 1 Bed rest and mental quietude
- 2 High carbohydrate diet, with limitation of protein, and the elimination of caffeine

- 3 Use of sedatives and judicious iodine therapy

Among the more common medical errors in the management of thyrotoxicosis seems to be the indiscriminate use of iodine for unduly protracted periods and in unwarranted amounts. In thyroid disease, there are many untoward effects of iodine that are serious. The routine established in hyperthyroidism by Plummer and Boothby—from 30 to 40 drops of Lugol's solution daily as a purely pre-operative measure—has apparently resulted in the widespread habit of giving large doses over long periods of time, as a medical treatment in all types of goiter. Many of the very cases ultimately most harmed improve so markedly the first two weeks that the treatment is often carried on to the stage of actual damage.

DR JAMES T CASE (Chicago) I have no definite convictions about the relative value of radiation and surgery. I have seen both methods used and noted failures in both.

I would like to make some remarks in relation to the palliatives which may be employed in tiding a thyroid patient over an emergency until such time as surgery may be employed. Dr Bartlett mentioned these. I would like to recall what he said and thank him for the courtesy in underscoring radiation.

First I would name iodine medication, but not for long periods. I do not think there is any palliative that can be continued over a great period of time without danger to the patient.

I would put ligation next because, after ligation of the thyroid vessels, usually the superior, if surgery is contemplated it must be done within two or three months at the latest or else the good done by the ligation will have passed.

I then put radiation. We will have to con-

cited—that patient is not well when we get through but he has thyrotoxicosis—sometimes tetany, sometimes hyperthyroidism

Myxedema is a different condition I aim to secure a temporary hypothyroid state in patients who were thyrotoxic Thyrotoxicosis is incompatible with the absence of sufficient thyroid to produce it

DR BARTLETT Dr Williams, I am sorry that I made an erroneous statement about thyroidism

The patient who has done the best in the experience of our clinic is the one who ends up with a basal rate of perhaps from —5 to 0 Now there is no mistake in that statement

The other class of patients to which I referred numbers those who have succeeded in living through a number of these crises of which Dr Plummer has spoken, who have not died on the way and have finally, as Dr Carter said, burned out—the heart has been so terribly impaired that the individual cannot get around, the liver, kidneys, and other organs have been so impaired that they do not function properly

DR WILLIAMS Dr Bartlett drew a different picture of his material from the rest of us and shows perhaps why we cannot get together, why our groups are different I know that the material mentioned by the medical side did not seem to have the picture of such seriousness and there were no deaths or emphasis on severity in the radiologic group That probably is the reason why it is hard for us to come to the same conclusion

I think we can draw this conclusion as Dr Jenkinson says, the medical men who keep on sending thyroid patients to the radiologists must be satisfied with the improvement under roentgen treatment The surgical men who keep getting cases from the medical men also must feel very contented with the work that they are doing

I have noticed some of these very earnest surgical converts among my medical friends who never send me a case for radiologic treatment They say, "Why, Doctor, I get results by referring my cases to surgery and why shouldn't I keep on?" And I would say that they should So we are all trying to understand a very difficult problem

cussions because they use different languages and they do not understand one another

In my work, every patient who fails to get complete relief from thyrotoxicosis, whose metabolic rate fails to drop to, or below, normal, is passed as a failure No case is passed as improved

The basis for that attitude is the idea that the patient who is merely improved is still toxic, though less toxic than previously He, therefore, is in the same need for proper medical or surgical care that he was when he came under treatment in the first place The patient whose basal metabolic rate has dropped from +60 to +40 under treatment is still just as much in need of treatment as if it has risen from +20 to +40 without treatment A rate of +40 in itself is indicative of the need for further treatment The patient, therefore, must be regarded as toxic and his previous treatment a failure I believe that patients treated by radiotherapy should be classified in the same way, and the group of so-called improved cases entirely eliminated, or, rather, transferred to the group of failures

This is illustrated by the paper of one of the speakers who had treated some thousand cases by radiotherapy, with approximately 70 per cent cures and 7 per cent failures There is a deficit of 23 per cent somewhere It seems to me that that 23 per cent should be added to the 7 per cent, making a total of failures of 30 per cent That is a crushing number of failures

Dr Plummer may be interested in the case reported by Dr Phemister of a patient who had a high-grade thyrotoxicosis He was operated upon two, or possibly three, times, the final operation disclosing only two tiny fragments of thyroid tissue The patient finally died of thyrotoxicosis At autopsy, no further thyroid tissue was found, though the autopsy had to be somewhat limited In the present state of our knowledge it is simply impossible to explain such a finding

DR ALDEN WILLIAMS (closing) I do not think we need be surprised that the radiologist feels in a haze and scarcely knows how to evaluate his own statistics He has only the one-sided view Dr Case, who is

both surgeon and radiologist, has a two-sided view and he admits that he is not certain which is the better method of treatment for this condition

I like very much Dr Bartlett's choice of words and his attitude of friendly fairness He did seem to make one little inconsistent remark, that the subthyroid patient was worth nothing to himself or to anyone else, also saying a little later that the milder subthyroids are the ones that stay well There must be real subthyroids and mild subthyroids

I perhaps did not hear distinctly when Dr Richter quoted his statistics I may be wrong—that he had just the two groups the cases which were considered rehabilitated and the cases considered failures

DR RICHTER All were failures that were not cures in Dr Bartlett's definition Every improved case was a failure

DR WILLIAMS I noticed that you were looking at our improved cases and placed them in the failures, and you did the same with your own In your failures, did you decide that from the elevated basal rate?

DR RICHTER Every patient was regarded as a failure whose metabolic rate was above +15, quite irrespective of other things at the time of the final report

With that there was the clinical study of the patient In these 18 cases, as I said before, if we did not absolutely include every case that showed this raised metabolism, we would exclude certain cases on account of the physical condition of the patient Every such patient was a failure

DR WILLIAMS Then I had in mind the subthyroid that follows the surgical work Were any of those considered failures?

DR RICHTER At the start, I said I would confine my paper to thyrotoxicosis If you amputate a leg for a carcinoma, though the patient would be a leg minus, he would be regarded as a cure The patient who has, for instance, a residual pathologic condition—damaged heart—a damaged leg in the example

ficiencies in certain of the long bones Professor Oluf Thomsen, Copenhagen, considers syndactylism unassociated with polydactylism as evidence of "less radical disturbance of the normal development." This last statement may seem unrelated to some of the foregoing, and yet study of the individual cases will prove the necessity for considering the importance of Professor Thomsen's statement in the light of biologic experimental data.

In 1898, Cotton and Chute (11), reported three cases of congenital defects of the fibula, and they stated

The amniotic theory seems to explain all lesions pretty clearly. We cannot but accept it as at least the most plausible theory yet advanced. The origin of the typical deformity would be, then, as follows: between the fifth and the eighth week, pressure of a too tightly fitting amnion interferes with the development of the exposed fibula and the outer toe or toes of the exposed foot. Lack of space determines the bend of the growing tibia, the adhesion which produces the so-called scar is a result of contact of the most salient point of the tibia with the enveloping wall. The persistent lack of growth of the whole limb is probably a result of deficient vessels and nerves due to the early pressure, as well as of the disease.

Tubby (40) states that "absence of the radius or fibula, though rare, is more common than absence of the ulna or tibia." In discussing theories relative to congenital defects in long bones, Tubby cites Henry Ling Taylor.

Taylor sums up two of the theories generally advocated (1) the primitive fin theory of Gegenbauer, and (2) the amniotic theory.

The second theory ascribes the anomalies to a mechanical cause, namely, the pressure of the amnion and deficiency of fluid at the time of development of the arms, namely, about the fifth week.

He, too, considers the amniotic theory the most plausible.

Whitman (45) states that congenital absence of the fibula is rare and gives a number of theories of origin. According to him

The cause of deformity, associated with absence of bone, may be either an original defect in the germ or it may be due to interference with its development. In some instances amniotic adhesions may be one of the predisposing causes.

In 1914, G. Potel (34) in a series of remarkable papers on congenital malformations of the limbs points out

All genuine malformations are of embryonic origin, namely, due to an original germinal error. The amnion may determine easily recognizable traumatic lesions, but has nothing to do with the pathogenesis of true malformations. The modifications of the initial embryonic type, known as malformations, are produced—no matter to what species the embryo belongs—according to two mechanisms histogenic variation and disease.

The primitive or plastic embryonic cells are endowed not only with an almost indefinite power of proliferation, but, moreover, they enclose the material for several differentiations, actually, at the onset, the material for all differentiations. When a modification of the medium or environment supervenes, the plastic cellular substance endeavors to adapt itself to the new vital conditions offered to it. It develops in an atypical manner, but what very distinctly characterizes this atypical evolution—is the mutation of the primitive type—is the correlated initial adaptation of all the elements which enter into the constitution of the modified organ. In the case of disease of the plastic cellular material, the protoplasm undergoes a more or less complete disintegration. The cell may die or it may suffer, in the latter case, the disease lasts a certain time the differentiations are diminished, modified, or even arrested. Gradually, recovery ensues and the phenomena of differentiation and proliferation

SKELETAL DISTURBANCES AND ANOMALIES¹

A CLINICAL REPORT AND A REVIEW OF THE LITERATURE

By ISIDORE COHN, M.D., F.A.C.S., Professor of Clinical Surgery, Tulane University,
Associate Senior Surgeon, Touro Infirmary, NEW ORLEANS, LOUISIANA

THIS report is based on a series of personally observed cases of skeletal disturbances and anomalies. It includes cases of syndactylyism, hypodactylyism, polydactylyism, one case in which the thumb had three phalanges, ectromelia, deficiencies of the fibula, absence of carpal bones, and fusion of carpal bones. I am including also cases of dyschondroplasia for reasons which will be developed in the body of the paper.

The literature, both American and foreign, abounds in clinical reports of similar cases, but there is so much confusion with reference to etiologic factors and so little attention paid by clinicians in their reports to the remarkable experimental and biologic studies of Dareste, Stockard, Bagg, and others that I am prompted to collate some of the literature.

The fantastic theories which have been offered, based purely on imaginative, non-existent factors, should be discarded in favor of experimentally proved evidence such as that advanced by Stockard and Bagg.

Popular tradition holds to the theory of primogeniture. Macklin (29) presented conclusive evidence that the first-born is not more liable to show hereditary defects than are the other children. After a study of 1,050 cases of defective children, she found that of these only 295, or 28 per cent, were first-born.

It is true, I believe, that all defects and deformities can be shown to be hereditary if we accept biologic experiments as sufficient proof. The absence of such proof in a particular patient is probably due to our in-

ability to obtain accurate information relative to his ancestry.

There are many theoretic explanations of the etiology of defects and deformities.

David Perkoff (33) mentions the following which have been advanced with reference to syndactylyism:

- 1 Lesions of the fetal nervous system (Guerin)
- 2 External pressure and traumatism during pregnancy (Cruveilhier)
- 3 Embryonic amniotic adhesion (Lannelongue)
- 4 Amniotic loops or bridles (Dareste)
- 5 Reversion to early conditions (Darwin)
- 6 Osler thinks it occurs more frequently in children of syphilitic appearance
- 7 Edwards states that it is a stigma of degeneration, occurring in persons of weakened intellect
- 8 Goldman asserts that syndactylyism may be regarded as an arrest of development since during fetal life the fingers are bound together for a time by webs of varying extent, the thumb almost always remains free, and in most instances two fingers only, usually the third and fourth, are bound together.

This is typical of the clinical papers. Many theories are presented, but no definite conclusions are drawn.

In order to correlate syndactylyism and other defects or skeletal disturbances, it must be remembered that in the literature the same theories of origin have been advanced for each.

Many defects and deformities may be found in the same individual, for instance, syndactylyism is frequently associated with polydactylyism, hypodactylyism, and de-

¹Presented before the Southern Surgical Association
White Sulphur Springs, Virginia Dec. 8 1931

pal bone, a supernumerary digit provided with a well formed nail. This digit had two phalanges, one of which articulated with the metacarpal bone. The thumb itself was nearly as long as the index finger, the appearance of which it simulated, and was provided with a metacarpal bone and with three phalanges, movable articulations existing between each of the members. The digit in question, though simulating the appearance of the other members of the series, was yet functionally a thumb.

Windle was able to find twelve such cases in the literature reported by Struthers, Runderger, Otto, Gegenbauer, Wenzel, Gruber, and Annandale. These cases are abstracted by Windle and anyone interested in the subject may well review the original articles.

In his discussion of the nature of the three-phalanged pollex, he says:

It will be observed that the three-phalanged pollex may exist (1) alone, representing the normal pollex, or (2), with a supernumerary pollex. In the latter case both pollex and supernumerary, or prepollex, may possess three phalanges. It will also be noted that, as in polydactylism, the influence of heredity is met with in several of the cases.

At the outset, we are met with the question as to whether these three-phalanged digits should be considered as of the nature of thumbs or not.

It will be noticed that in twelve cases the three-phalanged digit replaced the normal pollex and functioned as a thumb, being, in the instances in which any note is made of the fact, opposable to the other digit. To call such a digit an instance of a double index with (presumably) absent pollex, is, to my mind, a misuse of terms, unless, indeed, we are to confine the term 'pollex' to a two-phalanged digit, a limitation for which I can see no justification. A consideration of the musculature in cases of double pollex will, I think, establish the fact that these digits are much more of the nature of pollices than of that of the other digits.

His conclusions are:

1 That the three-phalanged pollex, when existing in a pendactylous manus, is not an example of duplication of an ordinary digit, but is a true thumb.

2 That the musculature shows that, in cases in which there is an additional digit on the radial side, it and the digit next to the index both partake of the nature of thumbs, and may be looked upon as the first and second digits of a heptadactylous manus.

We note also from Windle's work that he quotes Struthers, who believes that the metacarpal or metatarsal, respectively, has disappeared and that the normal condition is that the thumb has three phalanges. Struthers says:

The facts in comparative osteogeny show that the position of the epiphysis is decisive in establishing the view that the bone which is wanting in the human thumb and great toe, and in the internal digit of other five-toed mammals, is the metacarpal and metatarsal, although custom and convention lead us to apply these terms to the bone which, homologically, is the proximal phalanx.

Continuing with our study of cases representing skeletal disturbances and anomalies, we note that the hereditary character of congenital disturbances such as syndactylism, polydactylism, and deficiencies of particular bones is evident from the literature. The question of whether it represents a dominant or recessive character has been investigated clinically by Snyder (35). His evidence points to a definite recessive factor for polydactylism.

He says:

During the Summer of 1928, in connection with an intensive study of human blood groups, a large number of negroes in Pamlico County, North Carolina, were found, who showed an extra fifth finger on each hand.

are restored. But the momentary arrest has resulted in a loss of equilibrium, a local modification, which will manifest itself at birth under the aspect of a malformation. A classification of the congenital deformities is difficult.

All the varieties of localized osseous dystrophies, in spite of their apparent complexity, may be grouped under three principal headings:

- A* Developmental disturbances of the skeletal rudiments
 - 1 Ectromelias
 - 2 Hypertrophies
- B* Disturbances of segmentation
 - 1 Abnormal fusions of the segments
 - 2 Exaggerated segmentations

Exaggerated segmentation, resulting in polydactylysm, is a relatively frequent malformation. It may be said to be the prototype of the hereditary skeletal modifications. In certain observations, a thumb with three phalanges existed at the same time as polydactylysm.

- C* Axial deviation
- D* Superadded aberrant heteroplastic nuclei (osteogenic exostoses)

The various processes do not exclude each other and are even very often found associated in the same individual.

Bagg (2), discussing polydactylysm, states:

Stockard and others have shown that a reduplication of embryonic parts may be brought about experimentally by a temporary arrest of embryonic development at a critical growth period.

When the growing apical bud of a twig is arrested in development by pinching or other methods, dichotomous growth occurs, and as a result the two adjacent axillary buds, quiescent during the supremacy of the apical bud, begin to develop 'twin' branches. Similarly, Stockard has produced a reduplication of parts and marked degrees of twinning in trout embryos by arresting the development at a critical growth period.

Tubby (40), discussing polydactylysm, states:

The condition is often hereditary and may be traced through several generations, and frequently exists both in the toes and in the fingers.

It is difficult to speak of types, as the individual cases vary so much, but the most frequent form is a supernumerary little finger. Next to that is a double thumb, or pollex duplex. Sometimes the additional thumb possesses three phalanges.

The last statement is of particular significance because anyone who has studied the human hand and foot has noted that the metacarpals and metatarsals of the first digit, or thumb and great toe, have their epiphyses at the proximal end, while the epiphyses of the other metacarpals and metatarsals are found at the distal extremity.

One of the cases in this group presented a first digit with three phalanges, thus I originally considered an accessory index finger. The patient had a definite syndactyl condition of the first and second digits, and for this reason I do not know whether the musculature is that of the thumb or an index finger. Details of the case are included in the clinical section of the paper.

Observations similar to this have been made by Potel, Tubby, Windle, Struthers, and others. The most extensive study of this "anomaly" was made by Windle as long ago as 1892. He collected in all twelve cases, including his own. Because of the importance of the unsettled question of whether or not the thumb has, like other digits, three phalanges, the metacarpal disappearing in development, I am going to quote extensively from Windle's original paper.

Windle's patient had "five fingers and a thumb on one hand, and five fingers and no thumb on the other" (47). He found the following condition. The thumb on the left hand bore, on the radial side of its metacar-

the fetus at birth as a result of muscular contraction in parts which are retained in approximation during uterine life

Paralysis, due to a disease of the spinal cord, is a factor in the production of non-congenital club-foot in man, but such a cause can hardly be operative in congenital cases, because the leg in congenital talipes does not at all resemble the leg in infantile paralysis, and, if the deformity were due to a lesion in the central nervous system and paralysis resulting therefrom, not a single group of muscles, but a whole side of the body would be paralyzed, which is not the case in children with congenital club-feet.

The review given above leaves the question of the etiology of congenital club-feet and other congenital defects of the limbs entirely unsettled, and nowhere do I note reference to arrested embryonic development associated with a specific localized lesion in the clinical data upon which to base a tenable theory.

I shall briefly summarize the experimental results of the present communication before giving an explanation for the causation of foot defects as seen in my animals.

Over 5,200 individuals have been examined from my strain of inbred animals. They are descendants of the nineteenth generation of certain X-radiated mice. In this group, there has appeared a marked tendency to abnormal development. This tendency is inherited in approximately a mendelian fashion and is definitely recessive to the normal.

These observations indicate that clubbing and other defects of the limbs usually occur early in embryonic development and are first associated with localized arrests in development.

The results show still further that there is apparently an association between the degrees of severity of the pathological embryonic disturbance and, subsequently, the resultant type of foot abnormality. Congenital amputation in man has been ascribed to constriction of a fetal limb by either the umbilical cord or amniotic bands, but such an explanation does not fit the observed facts in my strain of animals.

Turning from Bagg to Stockard (36), we find that as early as 1920 he arrived at the following conclusions:

The ordinary progress of embryonic development gives rise to individuals of rather uniform structure, yet there may be numerous slight variations and defects in the structural composition of various organs and parts. When the same deviations become exaggerated they may be ranked as serious deformities or anomalies. This fact renders the analysis of normal developmental processes and the experimental study of monstrous development one and the same problem.

For the past two years I have claimed that all types of monsters not of hereditary origin are to be interpreted simply as developmental arrests. Such a position has been taken by others (Dareste, 1891). However, I propose, at this time, to present evidence which clearly demonstrates the truth of the claim.

First, all types of monster, double as well as single, may be caused by one and the same experimental treatment; second, any one type of monster, such as cyclopia, may be produced by a great number of different experimental treatments; third, all effective treatments tend, primarily, to lower the rate of development; and fourth, the type of monster induced depends upon the particular developmental moment during which the developmental rate was reduced. Slowing the rate at one moment will produce a double monster or identical twins and at another moment, by the same method, will give rise to the cyclopean defect. In fact, the same thing which causes the double monster may later in development induce one of its heads to be cyclopean.

Thus, there is no longer any ground for considering certain defects as specific responses to particular treatments. And there is as little reason for further description of individual monsters, since all belong to the same class and the individual differences simply result from the different moments during which the developmental interruptions have acted.

In view of experimental results, it becomes

Careful family histories were gathered, and the results are presented herewith

If one parent is polydactylous and the other normal, polydactylous children should make up at least half, and probably more, on the average, of the offspring, if the character is dominant. From 16 such matings, 24 polydactylous and 26 normal children are recorded. This is a slight bit of evidence for recessiveness. Two families are recorded in which, although one parent was polydactylous, all of the children were normal (in one case four, and in the other six), these are further indications of recessivity.

Summing up the evidence for recessiveness, the character does not fulfill the requirements for dominance (must occur in every generation, must show up on the average in half or more of the offspring), while it does meet the criteria for recessiveness (must be homozygous when it appears, as evidenced by the result of mating two individuals showing the character, may skip one or more generations and appear when neither parent shows the character).

He quotes other workers whose conclusions are not in agreement with his own.

Many cases of polydactylism are on record. The character appears to be regularly dominant, although in some instances it is imperfectly so. Thus, Lucas gives a family history in four generations in which there was one case of failure to dominate. Bellowitz gives several family histories in which polydactylism appears to be dominant. Miles considers the character as dominant. In poultry, polydactyly appears to be dominant.

In order to obtain first-hand information with reference to skeletal disturbances, we must turn to the writings of embryologists. Bagg and Stockard have done experimental work which may well be accepted as conclusive.

Bagg (2) states:

The origin of congenital defects of the limbs is a much confused subject. An inherited ten-

dency to limb abnormalities has been noted in certain families, but no satisfactory explanation for their origin has been offered.

Abnormalities of the limbs are definitely inherited. They are recessive to the normal inheritance. When considered as one of the manifestations of a general tendency to abnormal structure, they approach the mendelian expectation in behavior.

The occurrence of congenital amputation or the entire loss of the distal portion of a limb at birth is, in the mind of the writer, but an exaggerated or more severe form of the same arrested embryonic development that produced clubbing, syndactyly, and hypodactyly in these animals.

Discussing the theories which have been advanced by clinicians, Bagg says:

Congenital clubbing of the limbs in man has been attributed to accidental mechanical disturbances that produce unusual and prolonged pressure upon the fetus while developing in the uterus, to the absence of amniotic fluid, in consequence of which the uterus was thought to press directly upon the feet of the fetus and become an efficient cause for their turning, to an arrest in the rotation of the limbs before birth, in which case the feet retain their fetal position with the little toes facing one another, and, finally, clubbing of the limbs was thought to result mainly from disturbance in the central nervous system of the developing embryo.

The writer believes that pressure upon the fetus *in utero* is unlikely to produce clubbing of the limbs, especially as the defect has been noted in uterine life as early as the third month of gestation and is frequently met with in fetuses between the fourth and fifth months. Deficient amniotic fluid can hardly be a potent factor in the production of clubbing, as in many well observed cases of this kind, perfectly formed infants have been born, and *vice versa*. If the theory of retarded rotation of the limbs before birth in relation to the production of club-feet was at all tenable, then we would have to account for the absence of bent knee, bent thigh, bent arms, etc., in

Figs 1 and 2 Case 1 Complete syndactyly of the right hand

not bear out this, at operation we did find an additional terminal phalanx

The surgical problem involved in this case naturally consisted in trying to separate all of the fingers and to obtain a useful hand. On account of the age of the baby, it was decided to do several operations rather than one long operation. The end-result justified the means. The operative procedure followed was the Agnew operation, which I prefer because it provides for the formation of a web between each of the fingers.

Case 2 C S., aged 4 years. The diagnosis was syndactyly, the thumb presenting three phalanges (Figs 4, 5)

Physical Examination—Examination on June 4, 1930, showed that separation of the "webbing" had been attempted in a previous operation, but the fingers had grown back together again. The Diddo type of operation seemed to have been adopted.

On the left hand there were four fingers and a digit, which was shorter than the index finger and was webbed with the index finger at the junction of the middle and terminal phalanges. There was complete webbing of the digits which corresponded to the thumb and index finger. A scar of a previous operation, probably of the Diddo type, was present. There was slight flexion of the first digit.

Palpation of what I took to be the first metacarpal revealed a long, thin bone much smaller than the other metacarpals. There were three phalanges.

On the radial side of the index finger of the right hand there was a small nail and what probably was an accessory digit on the radial side of the index finger, giving the index finger a broad, but step-like, appearance. The terminal phalanx with the nail was slightly flexed.

Palpation just below the styloid of the radius revealed a small, apparently rudimentary, first metacarpal which had a sharp point, very much like a cypress knee. Below that I felt a metacarpal which was continuous with the index finger. On the outer side of the first phalanx of the index finger, there was a small, apparently rudimentary, first phalanx which was movable and seemed to have no fixed point above. I could make out two phalanges, definitely.

My impression was that we had an accessory index finger on the left hand, and an absence of a thumb, the reason I believed this was because there were three phalanges.

It will be seen that my first impression of this case was that the first digit was an extra index finger and not a thumb.

It has been shown, in the section of the paper in which the literature is reviewed,

evident that normal development of the vertebrate embryo depends acutely upon the stability of certain factors in the environment. Changes in the condition of moisture, temperature, and oxygen supply are the most frequent causes of embryonic death as well as monstrous development. The highly complex forms, such as birds and mammals, with a long embryonic period, have partially succeeded in controlling their developmental environment. But in no case is the regulation constantly perfect and this fact is the underlying cause of frequent malformations and monstrous productions.

Comparison of the above statements with the work of Struthers shows that these embryologists are in agreement.

In view of the biologic data which I have quoted, I feel that we should accept the evidence and discard the fanciful theories. Bagg has shown, definitely, that the amniotic adhesion theory of origin is not tenable. I mention this theory in particular because it seems to have arrested the attention of, and has been accepted by, Cotton and Chute, Tubby, Taylor, Windle, and other clinicians.

Summarizing the evidence, I think that we are justified in concluding:

- 1 Deformities and defects are hereditary.
- 2 They are due to arrests of development at a particular moment.
- 3 There is no good reason to attempt to classify hereditary defects, as they can be legion.
- 4 Considering the classic work of Potel, Bagg, Stockard, and Jansen, there is reason to consider that exostoses and other dissociation phenomena which appear after birth are the result of biologic arrests. This will be discussed more fully later.

CLINICAL REPORT

In this series there are three syndactyl cases, all of which are associated with additional evidence of disturbance of develop-

ment, thus bearing out the statement of Professor Thomsen, "Syndactylism unassociated with polydactyly is evidence of less radical disturbance of normal development."

Case 1 Baby G D, aged 8 months. There is no familial history of congenital malformations.

The patient was referred by Maud Loeber, M.D., with a diagnosis of syndactylism of the right hand (Figs. 1, 2, 3).

Physical Examination—The right hand showed five well developed fingers and thumb. There was a definite web which united all of the fingers and the thumb. All of the fingers, except the index finger, were well developed and their outlines were definitely made out. The index finger was broader than the thumb and the nail of the index finger showed a definite bifurcation. The breadth of the nail was 1.5 cm., the nails of the middle and ring fingers were a little over 0.75 centimeter. All fingers were flexed. The web between the thumb and index finger was very narrow. I could make out five first phalanges, but it seemed that the index finger had accessory second and third phalanges.

The X-ray films did not reveal any evidence of extra digits or an accessory phalanx as was indicated by clinical examination.

Three operations were deliberately planned and done before all of the fingers had been separated.

Comments—There was no history that the defect was a familial characteristic. There was one perfectly normal child in the family, born prior to this deformed child. The only defect which the patient exhibited was complete syndactylism of the right hand. The terminal phalanx of the index finger was twice as broad as its fellow on the opposite hand. The nail looked like a double nail, suggesting that there were accessory second and third phalanges on the index finger. Although the X-ray films did

Figs 1 and 2 Case 1 Complete syndactyly of the right hand

not bear out this, at operation we did find an additional terminal phalanx

The surgical problem involved in this case naturally consisted in trying to separate all of the fingers and to obtain a useful hand. On account of the age of the baby, it was decided to do several operations rather than one long operation. The end-result justified the means. The operative procedure followed was the Agnew operation, which I prefer because it provides for the formation of a web between each of the fingers.

Case 2 C S., aged 4 years. The diagnosis was syndactyly, the thumb presenting three phalanges (Figs 4, 5)

Physical Examination—Examination on June 4, 1930, showed that separation of the "webbing" had been attempted in a previous operation, but the fingers had grown back together again. The Diddo type of operation seemed to have been adopted.

On the left hand there were four fingers and a digit, which was shorter than the index finger and was webbed with the index finger at the junction of the middle and terminal phalanges. There was complete webbing of the digits which corresponded to the thumb and index finger. A scar of a previous operation probably of the Diddo type, was present. There was slight flexion of the first digit.

Palpation of what I took to be the first metacarpal revealed a long, thin bone much smaller than the other metacarpals. There were three phalanges.

On the radial side of the index finger of the right hand there was a small nail and what probably was an accessory digit on the radial side of the index finger, giving the index finger a broad, but step-like, appearance. The terminal phalanx with the nail was slightly flexed.

Palpation just below the styloid of the radius revealed a small, apparently rudimentary, first metacarpal which had a sharp point, very much like a cypress knee. Below that I felt a metacarpal which was continuous with the index finger. On the outer side of the first phalanx of the index finger, there was a small, apparently rudimentary, first phalanx which was movable and seemed to have no fixed point above. I could make out two phalanges, definitely.

My impression was that we had an accessory index finger on the left hand, and an absence of a thumb, the reason I believed this was because there were three phalanges.

It will be seen that my first impression of this case was that the first digit was an extra index finger and not a thumb.

It has been shown, in the section of the paper in which the literature is reviewed,

and also from the review of my own observations on normal bones and joints, that the position of the epiphysis of the first metacarpal corresponds with the epiphysis of the first phalanx of the other digits and not with the position of the epiphyses for the other metacarpals, thus suggesting the possibility that the first "metacarpal" is, in reality, a phalanx and not a metacarpal, and that in the evolution of the hand and foot there has been a loss of the first metacarpal for the first digit or thumb. This is an interesting problem in comparative anatomy and biologic evolution which may well form an independent thesis.

Case 3 The members of the family which we are about to discuss showed polydactyly as a dominant hereditary character. The mother had six well formed toes without evidence of syndactyly. The X-ray films showed five well formed metatarsals and an incompletely developed sixth. The first phalanges of the two great toes on each foot articulated with the first metatarsal. No phalanx articulated with the incompletely developed metatarsal.

This patient had six digits on each hand, the extra digit which was on the ulnar side of the little finger was shorter than the other fingers. Roentgenologically, this digit was seen to have two phalanges and an incompletely developed first phalanx (Figs. 6, 7, 8).

The daughter had seven digits on one foot and six on the other, apparently two well formed great toes on each foot, and each great toe articulated with its own metatarsal. In this respect the patient differed decidedly from the mother. On the left foot there were two well formed little toes, each articulating with a single metatarsal which was incompletely bifurcated in its distal 0.5 inch, giving the appearance of a fork thus forming separate articular surfaces for each first phalanx. On the right foot, each

Fig. 3 Case 1 X-ray film made two and one-half years after original operation for complete syndactyly.

of the six toes articulated with its own metatarsal.

The hands were identical. Each presented six digits with only five metacarpals. The sixth digit had no metacarpal of its own, but rested against the ulnar side of the fifth metacarpal (Figs. 9, 10, 11).

As surgeons, we are confronted with the problem of removal of the supernumerary toe or toes when the foot is too broad to be accommodated by the average shoe. In the case of the supernumerary digit on the fibula side of the little toe, there is little cause for discussion or doubt as to the proper procedure, but when it is a supernumerary great toe the question is one that requires study not only of the X-ray film, but also of the musculature of the respective toes. If the extensors and flexors are duplicated then it

does not matter, but if they are not, then one may, by chance, remove the wrong digit. This problem is more serious in the case of the hand if there are two thumbs, since the function of opposing the first digit, which

The left hand had a well formed thumb and two fingers which were completely united, and on the ulnar side of one of the fingers there was an angular deformity. On palpation this exhibited a blunt end and

Fig 4 Case 2 Syndactyly in a four-year-old child. The thumb has three phalanges

we call a thumb, to the other digits is entirely dependent on its particular musculature.

In view of the above facts this group of cases becomes of more than academic interest to the surgeon.

Case 4 J H, aged 20 years. The diagnosis was syndactyly, hypodactyly, ectromelia, and deficiency of the fibula (Figs 12, 13, 14).

Physical Examination—On Aug 5, 1930, examination showed the right hand to be very narrow. There was no evidence of a thumb. There were only two fingers, evidently a middle and ring finger, and there was complete syndactyly of these two. Apparently there were only two phalanges to both fingers. There were only two metacarpals palpable.

The patient was unable to make a fist completely. He was unable to grasp an object tightly, but, as the result of necessity, after flexing the interphalangeal joint he pulled backward on the forearm in order to hold the object.

seemed to give the impression of springing from the first phalanx. The unusual feature about it was the great length of the first phalanx of what seemed to be the index finger. While the index finger had three well formed phalanges, the other finger seemed to have only two, in other words, there seemed to be only one interphalangeal joint which I could make out. The first phalanx of the finger on the ulnar side was bifurcated near the distal end and had two articular surfaces. There were apparently two terminal phalanges.

The length of the index finger was 10 cm from the metacarpophalangeal joint to the tip, the length of the other was 8.5 centimeters. The length of the first phalanx of the index finger was 5 centimeters. The length of the right hand from the metacarpophalangeal joint to the tip of the finger was 6.5 cm, the other, not over 6 centimeters.

There was a marked deformity of the right lower extremity. The tibia was saber-

shaped and the foot was displaced laterally and backward so that the tibia was prominent on the inner side. There were only

to the upper epiphysis fused with the metaphysis, and a segment which corresponded to the lower epiphysis fused with the lower

Fig. 5 Case 2 The thumb with three phalanges

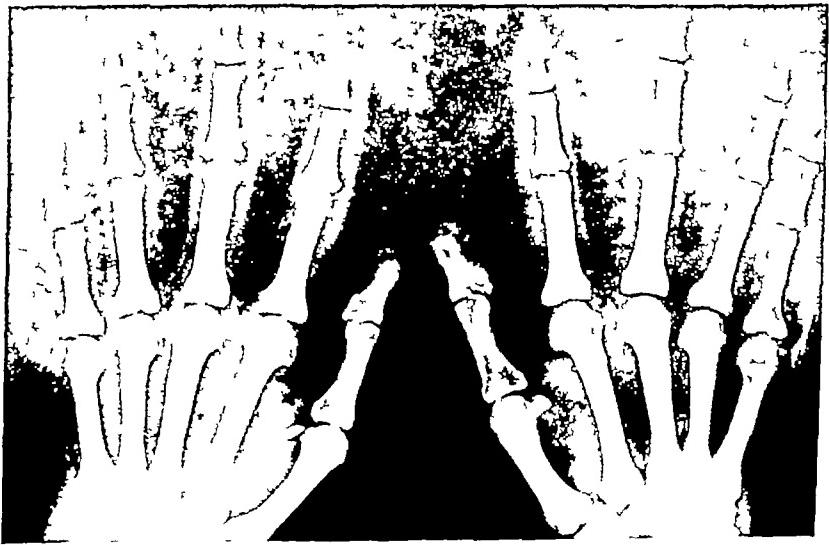

Fig. 6 Case 3 Polydactyly in the mother of 1 family which showed the anomaly as a dominant hereditary character

three toes and a great toe. There was no evidence roentgenologically of the midportion of the shaft of the fibula. There was a small segment of the fibula corresponding

metaphysis. The shaft was absent for the most part.

There was no deformity of the left leg, except that there were present only three

toes and a great toe. There was nothing suggestive of syndactylyism.

Unfortunately this patient disappeared after the examination was completed and it has been impossible to locate him.

Summarizing the clinical findings in this case there are certain conclusions which seem justifiable:

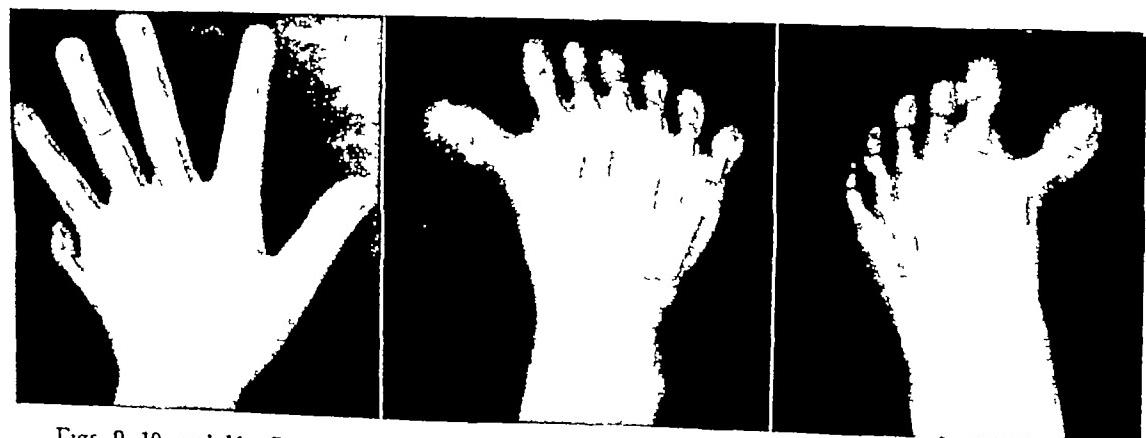

1. There is a definite hypodactylyism, more marked on the right than on the left.

2. There are only two fingers on the right hand and three on the left, with evidence of an arrested development which causes a bifid appearance of the terminal portion of one of the phalanges.

3. On the right hand there are only two carpal bones to be seen roentgenologically, thus we may say there is an absence of six carpal bones on the right, and on the left hand there seems to be a fusion of some of

Figs 7 and 8 Case 3. Films of the right and left feet, showing incompletely developed sixth metatarsal on each foot.

Figs 9, 10, and 11 Case 3. Feet and hand of daughter in family with hereditary polydactylyism. The hands were identical, each presenting six digits with only five metacarpals.

the carpals so that I can make out only three distinctly

4 There is an absence of the major portion of the shaft of the fibula. The upper and lower epiphyses appear, with a small

formed digit on the left hand was the thumb. There was a small bud which looked like an abortive attempt at a little finger. There was limitation of supination and limitation of flexion of the elbow.

Fig. 12 Case 4. The patient exhibited syndactyly, hypodactyly, deficiency of fibula, and ectromelia.

portion of the upper and lower portions of the diaphyses attached to them

5 There is a fusion of some of the tarsal bones on the right and a hypodactyl and syndactyl condition present in both feet

This case seems to bear testimony to the truth of the observations of Bagg and Stockard, that along with hereditary factors there must have been a developmental arrest responsible for the findings. The great variety of defects cited in this case could not well be accounted for in any other way.

Case 5 W P, age 9 years. The diagnosis was ectromelia (Figs. 15, 16, 17, 18)

Physical Examination—The entire upper extremity on the left was very much smaller and shorter than on the right. The only well

X-ray films were made of both shoulders, both elbows, and both hands.

This case is one of the most interesting of all the skeletal defects and disturbances that I have seen. We see that one of the upper extremities presents, at the shoulder and elbow, the appearance of at least one year's difference in skeletal growth. At the wrists there is even a greater divergence in the skeletal ages, the right wrist being that of a child of nine years, while the left appears that of a child between five and six years of age. Only one digit on the left hand has well formed phalanges. There are two distinct well-formed metacarpals and three that are rudimentary. The entire upper extremity on the left is shorter than on the right.

This case, I believe, can be explained only as a developmental arrest.

It would be futile to try to present cases from the literature as this would serve no useful purpose, not even for classification. Any attempt at classification except in a general way would be ridiculous. There are millions of possible combinations of defects and we might as well satisfy ourselves with the conclusions of Stockard "There is little reason for further description of individual monsters as all belong to the same class and the individual differences simply result from the different period during which the developmental interruptions have acted." Extensive articles have been written in all languages and these are referred to in the bibliography.

DYSCHONDROPLASIA

We come now to the phase of the subject which is most confusing and the conclusions at which I arrive are certainly in a controversial field. Even so, the suggestions which are here made may stimulate those well qualified to prove or disprove my statements.

I believe that the evidence which has been collected indicates that dyschondroplasia and other congenital deformities are identical in origin.

I have been especially impressed by the marvelous work of Jansen, and at the same time with the evident neglect of his important conclusions by many recent observers. Let me say at the outset that I believe with Jansen that dyschondroplasia is distinctly a dissociation phenomenon.

A careful study of his conception of the various factors involved in normal bone growth and the dissociation phenomena which give rise to exostoses cannot help but be profitable.

Before proceeding further it may be well to review the literature "Dyschondroplasia," "dissociation phenomena," "multiple epiphyseal chondromas," "exostoses" and

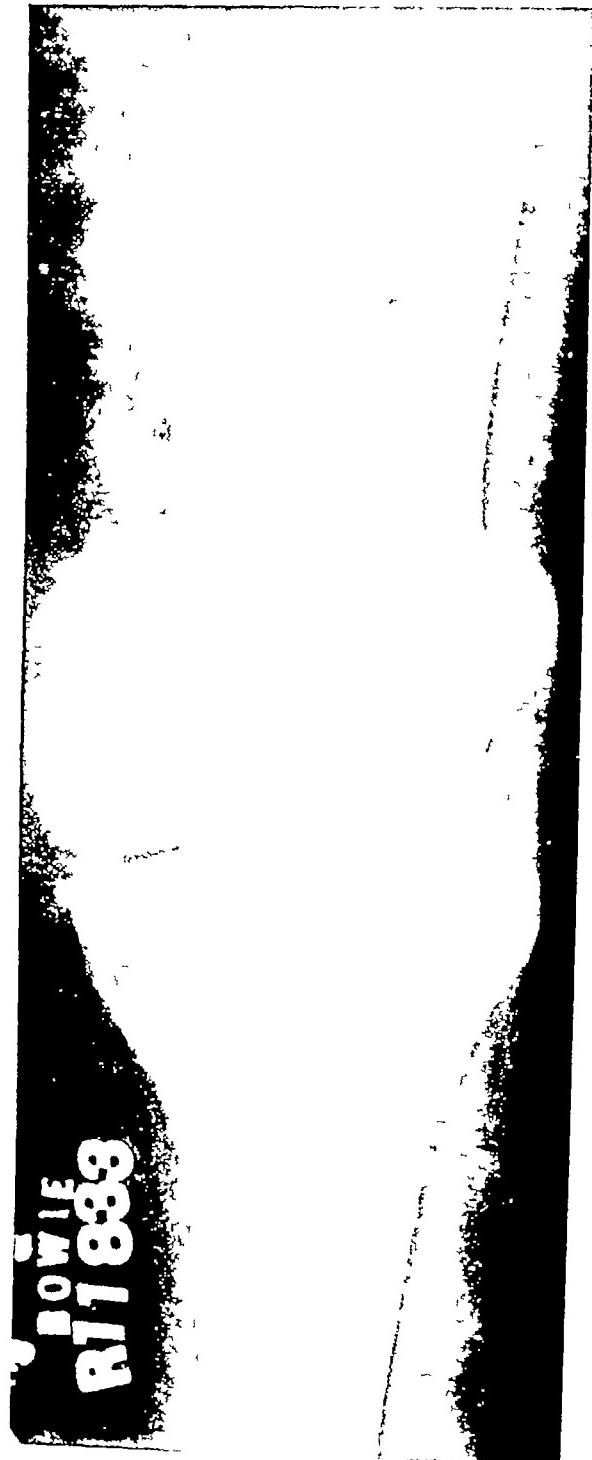

Fig. 13 Case 4 Defect in the fibula and absence

many other names have been used to describe a skeletal disturbance, reference to which is not uncommon in the literature. According to G. G. Davis the condition was

described by Caesar Hawkins in 1837. The first case to be reported in the United States was by Virgil B. Gibney (19) on March 24, 1875, when he presented at the New York Pathological Society a boy of 13 years who

Many of the earlier writers attempted to prove the association between multiple exostoses and achondroplasia. Jansen reports that Bessel-Hagen, in 1891, found that, almost without exception, patients who had

Fig. 14. Case 4. Radiograms give no evidence of the midportion of the shaft of the fibula.

had well marked exostoses on the upper end of each tibia and the proximal end of each humerus, and one on the left index finger.

Gibney again presented this patient before the same Society on April 23, 1897.

In 1876 he reported a Prussian family in which there were six members affected with the disease. These six patients represented three generations, one in the first generation, two in the second and three in the third generation.

multiple exostoses showed a stunting of growth.

Jansen also quotes Fischer, who described giant-growth in three members of a family who presented exostoses. Others, notably French authors, have described gigantism in cases of multiple exostoses. "Stunting of growth is not to be considered as a symptom associated with multiple exostoses."

In 1898, Ollier reported two cases of cartilaginous dystrophy in which the extremi-

ties of one side of the body were markedly retarded in growth, and to which he gave the name of dyschondroplasia. He defined dyschondroplasia as "an affection of the period of growth, with arrest of growing

view by partial arrest of development of the skeleton

2 The disturbance of the bony growth affects by preference the long bones of the extremities and the metacarpophalangeal skeleton of the hand

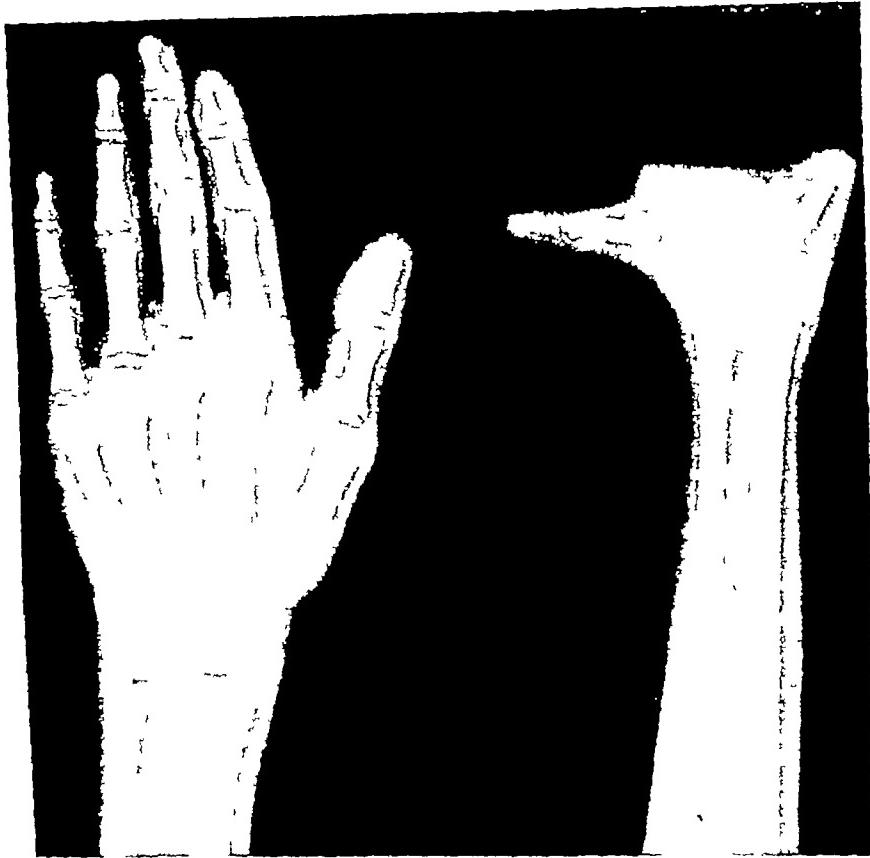

Fig. 15. Case 5. Ectromelia in a nine-year-old patient. Great divergence in the skeletal ages is shown, the right wrist being that of a child of nine, and the left having the appearance of that of a child of from five to six years old.

parts of the skeleton, with nodosities and swellings of the extremities of the corresponding long bones, curving of diaphyses and slight but constant deformities of the hands." He considered one-sidedness characteristic of the disease.

In 1910, Molin, a pupil of Ollier, published a thesis at Lyons entitled "Dyschondroplasia." His conclusions were

1 Dyschondroplasia is an osseous dystrophy characterized from a clinical point of

3 The long bones show curvatures analogous to those of rickets

4 Joint deformities must be considered as the direct consequence of bony alterations

5 Only the roentgenograph allows the nature of the dystrophy to be observed, it approaches that of rickets and chondroma but does not completely simulate them

6 The definite isolation of this condition cannot be made on account of the absence of complete microscopic findings

7 The identity of dyschondroplasia and

Fig 16 Case 5 Right shoulder

Fig 17 Case 5 Left shoulder Comparison of this view with Fig 16 shows the difference in skeletal growth when compared with the right shoulder

osteogenic exostoses needs further pathologic-anatomic control

8 The etiology is absolutely unknown
(Quoted from Cole)

It should be noted that Mohn and Ollier suggested a partial arrest of the development of the skeleton and that the identity of dyschondroplasia and exostoses needed further investigation. When one considers that this was thirty-one years ago, it is rather interesting to note that such an early lead was not followed up. While it is true that others in America have discussed the disease and reported individual cases, the excellent review of the literature by Ehrenfried, in 1915, has been most extensively quoted by subsequent writers. He was able to collect over three hundred articles representing about 600 cases, the majority of

which had been reported by German, French, and English writers. Up to that time Ehrenfried was able to find only 12 cases which had been reported in America.

Ehrenfried (15) stated, "A great deal has been written about the pathology and much confusion exists at the present time [1915]." This confusion he believes to be due to the fact that "most of the theories date to pre-*roentgen* days, and that the attention of the pathologists has been directed toward the relatively unimportant exostosis, rather than to the intermediary cartilage at the epiphyseal line." He believes that the theory of the inheritance of a faulty anlage for the bone-producing intermediary cartilage is still accepted. He states, "The disease consists, in brief, of a disturbance in the process of proliferation and ossification at the intermediary cartilage during the period of skeletal growth."

Comment.—Note that Ehrenfried considered that the disturbance occurred during the period of growth. My thesis is that the arrest occurs prior to birth and manifests itself during the growth period.

When discussing the characteristics of the disease Ehrenfried states

The skeletal disturbance and malformations are generally symmetrical for the two sides of the body. The affection is distinctly one of the period of skeletal growth. Manifestations increase with skeletal growth and cease with

Fig 18 Case 5 The difference in skeletal growth is shown by X-ray films of the elbows

maturity. Generally the cases have shown irregular juxta-epiphyseal hyperostoses, particularly marked at the knee, hip, shoulder, ankle, and wrist. The lower end of the femur and the upper end of the tibia have shown a characteristic squaring off, with spurs at the corner, running upward from the femur and downward from the tibia.

H. W. Marshall (30) made no attempt to discuss the theories of origin for, he says, "None can be proved beyond question. No observations have been made that are antagonistic to Ehrenfried."

Ashurst states, "The underlying pathologic change in cases of this sort is a chondrodysplasia affecting the metaphyses of the long bones, with the exostoses being merely incidental and not the essence of the disease" (*Quoted by Cole*)

After reporting a personally observed case and reviewing the literature Cole concludes

1 'Ollier's disease' is a term which seems fixed in the literature but which should be used to designate only those cases of cartilaginous dystrophy with or without cartilaginous tumor or exostosis formation, which show an asymmetrical involvement of the body as the outstanding clinical feature.

2 'Chondrodysplasia' (a term preferable to 'dyschondroplasia') is a condition which is usually asymmetrical but as several symmetrical cases are on record the term must, therefore, be broader in its application than 'Ollier's disease.'

The gradation of reported cases between those of frank multiple cartilaginous exostoses, on the one hand, and the so-called chondrodysplasia with no change in anything but the internal architecture of the bones (Voorhoeve cases), on the other, is so varied and irregular that a definite classification of cartilaginous dystrophy is still impossible. The possibility that the apparently widely different findings in some of these cases are only manifestations of different stages of the same condition must not be overlooked.

It should be remarked that Cole would

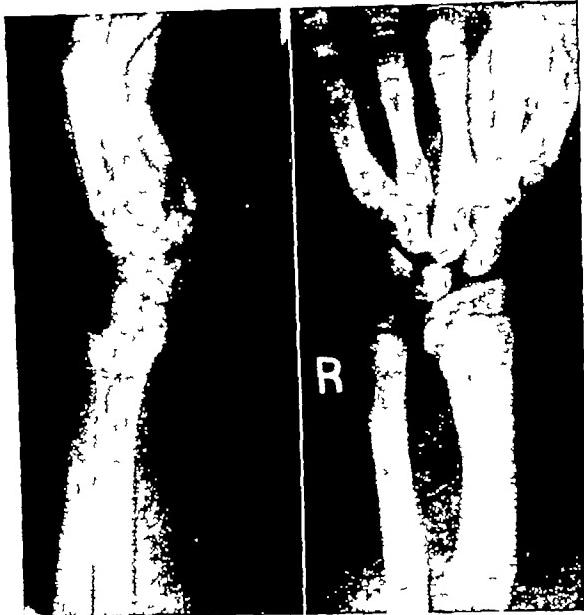

Fig. 19 Case 6 Dyschondroplasia accompanied by marked bowing of the forearm, which was more noticeable on the dorsum of the forearm when it was pronated (Film made in 1921)

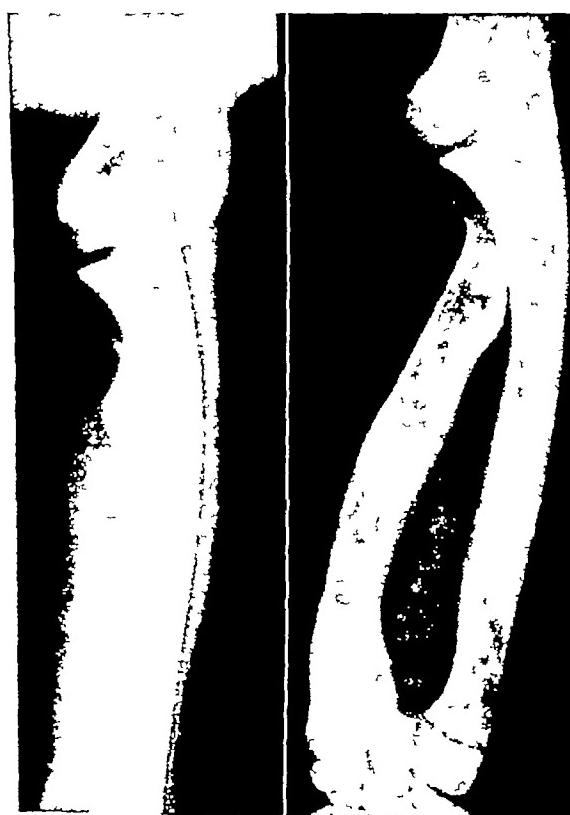

Fig. 20 The same case, from an X-ray film made in 1926

restrict the use of the name "Ollier's" to an asymmetrical skeletal retardation. It is interesting to note particularly Cole's final conclusions in which he speculated about that which seems to have been conclusively proved by Jansen's more recent work.

Sir Arthur Keith (26) stated

Multiple exostoses is usually placed by surgeons in the category of tumors, but a close examination of anatomic changes shows that it should be definitely placed among the disorders of growth and given a name to indicate its true nature. The name I propose, one suggested to me by Mr. Morley Roberts, is 'diaphyseal aclasis,' because the main incidence of the disturbance falls upon the modelling or pruning of the diaphyses or shafts of bones.

Characteristically, Sir Arthur Keith was able to find in his industrious researches that John Hunter had laid the foundation for what seems to be to-day the most logical conception of this condition.

Quoting Sir Arthur Keith

One of John Hunter's more important discoveries was his realization that the shafts of new bone grew in length by a double process; there was first the deposition of new bone in the cartilaginous growth disc at the ends of the shaft, a process clearly recognized before Hunter's time, there was in the second place 'a modelling process' by which the new bone thus laid down was pruned, reformed, and incorporated as an intrinsic architectural part of the cylindrical shaft. Hunter clearly recognized that these two processes were independent operations. If Hunter's teaching is true, then we ought to find disorders of growth in which deposition of new bone goes on while the second, or remodelling, process is retarded or even completely arrested. A survey of the skiagrams of the first case of multiple exostoses that came my way showed me that in this disorder the deposition process goes on, but the modelling process is retarded and aberrant. In multiple exostoses, which is

a disorder of youth and of adolescence, then, the modelling process is profoundly retarded, in some instances almost arrested. The bony excrescences, or tumors, which serve as diagnostic marks for the clinical recognition of the condition, are merely secondary results of the primary disorder of growth for which I propose the name of 'diaphyseal aclasis.'

Bentzen, in 1924, concluded

Ollier's disease represents the typical reaction of the bones against certain disorders in the innervation of their blood vessels. It is often confined to one-half the body. Masses of hyaline cartilage are found to follow paths similar to those of the arteries of the bones. The pathologic processes in the bone tissue may be assumed to be related to the formation of callus in a fracture in which the blood vessels have been interrupted. (*Quoted from Cleveland, 7*)

Cleveland stated

Bentzen disagrees with Ollier and Wittek, who described the disease as a disturbance of epiphyseal growth. He regards this as a secondary phenomenon. The primary focus is, he believes, in the diaphyses, which are nourished by a single large nutrient artery. From an experimental standpoint, working with rabbits, he was able, by interrupting the sympathetic nerves, in some instances to produce structural changes in bone similar to those seen in Ollier's disease. Bentzen's theories of the etiology of Ollier's disease, supported by his studies, form a valuable contribution.

In 1910 Gossage and Carling (22) emphasized the hereditary nature of the condition. The confusion which existed at that time with regard to the condition is illustrated by the following statement quoted from Gossage and Carling: "There is undoubtedly some relationship between cartilaginous exostoses and multiple enchondromas and of both with the peculiar disturbance of growth described by Ollier and known as 'dyschondroplasia'."

From the above it can be seen that those authors looked upon the condition as three separate entities, but with some relationship

In 1913, Thomas R Boggs (4) discussing multiple congenital osteochondromas, stated "There is much reason to accept the view that these tumors are truly congenital and due to abnormal anlage in the intermediary cartilage (*von Bergmann*)"

In 1915, R D Carman and A O Fisher (6) also accepted the theory expressed by von Bergmann Quoting from their work we find "The general involvement of the epiphyses, with the relative freedom from involvement of the shafts, is very striking and seems to support the most plausible theory advanced by von Bergmann and others with reference to the etiology of this condition, namely, that the lesions arise in abnormal anlage in the intermediary cartilage"

Again in 1925 Horace E Campbell (5) expressed the belief that "the most probable explanation is that there is a disturbance in development of the intermediate cartilage due to an original defective anlage" He further states that there is "little known concerning the etiology"

In 1930, Olan R Hyndman (23) stated

Like practically all of the hereditary disease entities of the skeleton, the etiology of chondrodyplasia remains a mystery

Although the primary factor is not established, it would seem to me that at least one fact is tenable and clear, that cartilage rests are left in the wake of a chaotic advancing epiphysis, and these rests undoubtedly form the nucleus of the anomalous benign tumors

Up to this time very little attention had been paid to the work of Murk Jansen and of Sir Arthur Keith, and, with the exception of Keith's brief mentioned statements of John Hunter, little or no attention was paid to the undeveloped ideas of dissociation of bone growth to which John Hunter gave a definite clue Great credit is due Jansen,

and his views should be more generally accepted I believe many of the conditions which to-day are considered separate entities will probably eventually be included under retardation phenomena after the significance of Jansen's work is more generally appreciated It is difficult to abstract this study briefly and for that reason I will quote rather extensively from the original surgical essay which appeared in the Jones Birthday Volume

Jansen states

Six different processes, and probably more, have to co-operate harmoniously in order that the bones shall attain their proper size, shape, structure, and composition when completing their growth These processes are resorption, tubulation (*i.e.*, the transformation of metaphysis into diaphysis), cancellation (*i.e.*, the formation of cancellous tissue), cell division, cell enlargement, and differentiation Sometimes one or more of these processes will be delayed with regard to the other processes during a shorter or longer period, *i.e.*, dissociates itself from those processes And the dissociation of each of these processes evokes its own characteristic symptoms which for the present may be concisely stated in the tabulation on the following page

The cause of dissociation of growth probably lies in disturbance of the sympathetic nervous system, through which either a defect or an excess of elements for bone growth is furnished

The clinical picture, according to Jansen, is characterized by its extreme polymorphism In some cases only a single bone is found to be affected and in others the condition presents itself on both sides I mention this statement because in one of our cases the retardation phenomena are limited to a single bone, the radius on one side, and in the other cases there is evidence of retardation phenomena in almost all of the bones of the skeleton, except the skull and vertebræ

restrict the use of the name "Ollier's" to an asymmetrical skeletal retardation. It is interesting to note particularly Cole's final conclusions in which he speculated about that which seems to have been conclusively proved by Jansen's more recent work.

Sir Arthur Keith (26) stated

Multiple exostoses is usually placed by surgeons in the category of tumors, but a close examination of anatomic changes shows that it should be definitely placed among the disorders of growth and given a name to indicate its true nature. The name I propose, one suggested to me by Mr. Morley Roberts, is 'diaphyseal aclasis,' because the main incidence of the disturbance falls upon the modelling or pruning of the diaphyses or shafts of bones.

Characteristically, Sir Arthur Keith was able to find in his industrious researches that John Hunter had laid the foundation for what seems to be to-day the most logical conception of this condition.

Quoting Sir Arthur Keith

One of John Hunter's more important discoveries was his realization that the shafts of new bone grew in length by a double process; there was first the deposition of new bone in the cartilaginous growth disc at the ends of the shaft, a process clearly recognized before Hunter's time, there was in the second place 'a modelling process' by which the new bone thus laid down was pruned, reformed, and incorporated as an intrinsic architectural part of the cylindrical shaft. Hunter clearly recognized that these two processes were independent operations. If Hunter's teaching is true, then we ought to find disorders of growth in which deposition of new bone goes on while the second, or remodelling, process is retarded or even completely arrested. A survey of the skiographs of the first case of multiple exostoses that came my way showed me that in this disorder the deposition process goes on, but the modelling process is retarded and aberrant. In multiple exostoses, which is

a disorder of youth and of adolescence, then, the modelling process is profoundly retarded, in some instances almost arrested. The bony excrescences, or tumors, which serve as diagnostic marks for the clinical recognition of the condition, are merely secondary results of the primary disorder of growth for which I propose the name of 'diaphyseal aclasis.'

Bentzen, in 1924, concluded

Ollier's disease represents the typical reaction of the bones against certain disorders in the innervation of their blood vessels. It is often confined to one-half the body. Masses of hyaline cartilage are found to follow paths similar to those of the arteries of the bones. The pathologic processes in the bone tissue may be assumed to be related to the formation of callus in a fracture in which the blood vessels have been interrupted. (*Quoted from Cleveland, 7*)

Cleveland stated

Bentzen disagrees with Ollier and Wittek, who described the disease as a disturbance of epiphyseal growth. He regards this as a secondary phenomenon. The primary focus is, he believes, in the diaphyses, which are nourished by a single large nutrient artery. From an experimental standpoint, working with rabbits, he was able, by interrupting the sympathetic nerves, in some instances to produce structural changes in bone similar to those seen in Ollier's disease. Bentzen's theories of the etiology of Ollier's disease, supported by his studies, form a valuable contribution.

In 1910 Gossage and Carling (22) emphasized the hereditary nature of the condition. The confusion which existed at that time with regard to the condition is illustrated by the following statement quoted from Gossage and Carling. "There is undoubtedly some relationship between cartilaginous exostoses and multiple enchondromas and of both with the peculiar disturbance of growth described by Ollier and known as 'dyschondroplasia'."

From the above it can be seen that those authors looked upon the condition as three separate entities, but with some relationship

In 1913, Thomas R Boggs (4) discussing multiple congenital osteochondromas, stated "There is much reason to accept the view that these tumors are truly congenital and due to abnormal anlage in the intermediary cartilage (*von Bergmann*)"

In 1915, R D Carman and A O Fisher (6) also accepted the theory expressed by von Bergmann. Quoting from their work we find "The general involvement of the epiphyses, with the relative freedom from involvement of the shafts, is very striking and seems to support the most plausible theory advanced by von Bergmann and others with reference to the etiology of this condition, namely, that the lesions arise in abnormal anlage in the intermediary cartilage"

Again in 1925 Horace E Campbell (5) expressed the belief that "the most probable explanation is that there is a disturbance in development of the intermediate cartilage due to an original defective anlage". He further states that there is "little known concerning the etiology"

In 1930, Olan R Hyndman (23) stated

Like practically all of the hereditary disease entities of the skeleton, the etiology of chondrodysplasia remains a mystery

Although the primary factor is not established, it would seem to me that at least one fact is tenable and clear, that cartilage rests are left in the wake of a chaotic advancing epiphysis, and these rests undoubtedly form the nucleus of the anomalous benign tumors

Up to this time very little attention had been paid to the work of Murk Jansen and of Sir Arthur Keith, and, with the exception of Keith's brief mentioned statements of John Hunter, little or no attention was paid to the undeveloped ideas of dissociation of bone growth to which John Hunter gave a definite clue. Great credit is due Jansen,

and his views should be more generally accepted. I believe many of the conditions which to-day are considered separate entities will probably eventually be included under retardation phenomena after the significance of Jansen's work is more generally appreciated. It is difficult to abstract this study briefly and for that reason I will quote rather extensively from the original surgical essay which appeared in the Jones Birthday Volume

Jansen states.

Six different processes, and probably more, have to co-operate harmoniously in order that the bones shall attain their proper size, shape, structure, and composition when completing their growth. These processes are resorption, tubulation (*i.e.*, the transformation of metaphysis into diaphysis), cancellation (*i.e.*, the formation of cancellous tissue), cell division, cell enlargement, and differentiation. Sometimes one or more of these processes will be delayed with regard to the other processes during a shorter or longer period, *i.e.*, dissociates itself from those processes. And the dissociation of each of these processes evokes its own characteristic symptoms which for the present may be concisely stated in the tabulation on the following page.

The cause of dissociation of growth probably lies in disturbance of the sympathetic nervous system, through which either a defect or an excess of elements for bone growth is furnished.

The clinical picture, according to Jansen, is characterized by its extreme polymorphism. In some cases only a single bone is found to be affected and in others the condition presents itself on both sides. I mention this statement because in one of our cases the retardation phenomena are limited to a single bone, the radius on one side, and in the other cases there is evidence of retardation phenomena in almost all of the bones of the skeleton, except the skull and vertebrae.

| | Causes |
|---|---|
| Dissociation (through retardation) | |
| Of resorption, e.g., of the tuberosity of the ribs, of the trochanters, the obturator borders of the ischial and pubic bones, or also in the meatus auditorius externus | Exostoses Too wide ischial and pubic bones (a two small obturator foramen) |
| Of tubulation | |
| (a) Over the whole circumference of | (a) Lengthened metaphyses |
| (b) Over part of the circumference | (b) Exostoses |
| Of cancellation | Striated and mottled metaphyses |
| Of cell division | |
| (a) Over the whole area of the growth cartilage | (a) Thin, eventually, invisible, discs and shortened bones |
| (b) Over part of the area of the growth cartilage | (b) Obliquely situated or cone- or cupola-shaped, irregular growth discs with varus-valgus flexion or hyperextension positions of the long bones. |
| Of cell enlargement (?) | |
| Of cell differentiation | Chondroma, enchondromas, giant-cell tumors, i.e., dissociation tumors |

Jansen emphasizes that any symptom may predominate in the clinical picture and "The symptoms may be associated with the other symptoms in every conceivable combination and in every imaginable locality though only in the bones formed in cartilage"

PATHOGENESIS

Discussing pathogenesis Jansen says

It should be remembered that during the growth of bone, resorption of the metaphyses has to keep pace with longitudinal growth

During growth the epiphysis is displaced distally by the growth disc, the metaphysis is not. The processes of resorption of the cancellous tissue and its transformation into the compact diaphyseal tube we will call 'tubulation of the metaphysis' or, shortly, 'tubulation'. It stands to reason that only if the tubulation keeps pace with the longitudinal growth of the bone will the normal funnel shape of the diaphysis end lie close to the epiphysis, whereas an approximately cylindrical area of cancellous tissue produced by the growth disc must be expected to lie between the funnel-shaped end of the metaphysis and the growth cartilage, when tubulation is retarded. Hence, the conclusion presents itself that the cylindrical or barrel-shaped area between the growth cartilage and the funnel-shaped metaphysis, which we will call 'lengthened metaphysis,' is caused by a retardation or tubulation, i.e., by a dissociation of tubulation

from the processes of longitudinal growth through either relative or absolute retardation

What causes the local impediment to tubulation is as yet unknown

Taking everything into consideration, we cannot help believing that the lengthened metaphysis is the result of a retardation of tubulation over the whole periphery of the bone, i.e., a total retardation of tubulation, and the exostoses a partial retardation of tubulation, i.e., these two phenomena appear to us as the result of a total and a partial dissociation through retardation of tubulation with regard to the other processes of longitudinal growth

Virchow, Ollier, and all other authors, as well as ourselves, consider enchondromas to be caused by the failure of one of the growth processes, viz., by what in the above has been termed 'dissociation of one of the growth processes through retardation with regard to the others'

According to Virchow, exostoses are caused by a stimulation of the growth cartilage which evokes undue lateral growth

There is no denying that the picture of the development of exostoses sketched by Virchow is anything but clear. 'Stimulation [by what?] of the growth cartilage' causes 'undue [why?] lateral [why and how?] growth'. If this were correct, this cartilage would have to start its growth from the side opposite to that from which it grows normally

We are tempted to assume that each of the processes of bone growth may be retarded with regard to the others, either over the

whole area of its activity in a bone (total dissociation) or in part of it (partial dissociation), each dissociation leading to characteristic phenomena

Total retardation of cell division in a growth disc causes thinning of the growth disc, shortening of the bone, and trumpeting of the metaphysis,

Partial retardation of cell division causes deformations of obliquity of the growth disc and deformities in the bone,

Total retardation of differentiation causes cartilaginous metaphysis,

Partial retardation of differentiation causes clear areas in the bones. Both total and partial retardation may form tumors (dissociation tumors),

Retardation of cancellation causes gross longitudinal striation—and, possibly, also dense stippling (?),

Total retardation of tubulation leads to lengthened metaphysis,

Partial retardation of tubulation leads to the development of exostoses, whilst

Retardation of resorption leads to the development of widened bones, enlarged apophyses, and probably also of button-shaped exostoses on the ribs

Geschickter (18), in a recent contribution, discusses dyschondroplasia, saying

The fundamental basis of the congenital disturbance is obscure, but deficiencies in the periosteum and a tendency for the perichondrium to persist and to function as such, together with precartilaginous connective tissue about the joints, seem to be responsible for most of the deformities. The process is extremely complicated but it shows what a fine state of balance among various tissues of similar function is necessary to produce the normal

One will note from the above quotation that Geschickter comes very close in his conclusions to those of Jansen, but apparently he feels still uncertain about the underlying cause. However, his realization that there is a fine balance among various tissues and

Fig. 21 The same case as shown in Figures 19 and 20, from a film made in 1927

similar functions necessary to produce normal shows a definite leaning toward Jansen's conclusions

Wahren's (44) clinical experience appears to support and illustrate clearly the theory of Murk Jansen. Wahren states

The exostoses and the elongation of the metaphyses are co-ordinated symptoms which develop through an inhibition of that process which effects during growth a metamorphosis of the metaphysis into diaphysis. This process is termed 'tubulation' by Murk Jansen

This brief summary of the literature justifies, I believe, certain conclusions

1 Dyschondroplasia and other congenital deformities are identical in origin

2 Dyschondroplasia is evidence of retardation or dissociation phenomena in bone growth. Such phenomena may be partial

DYSCHONDROPLASIA

The first case to be presented is of particular interest because the manifestations of the "disturbance" are limited to one bone.

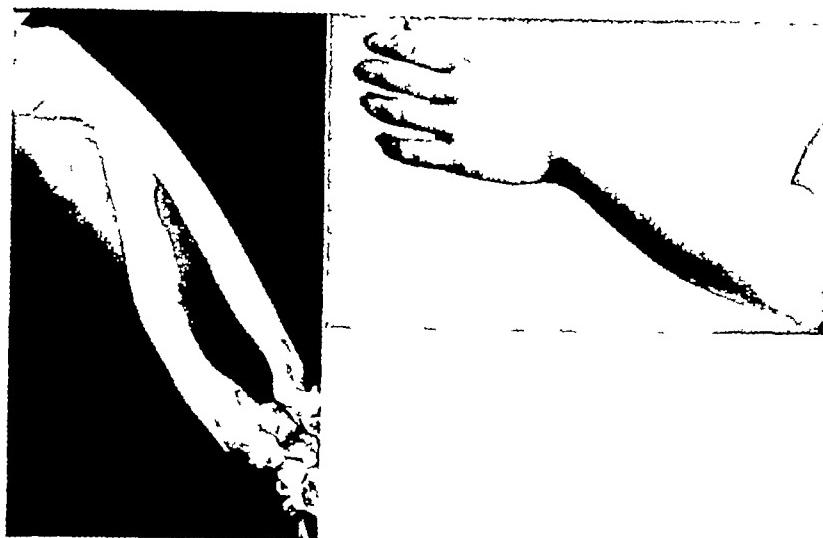

Fig. 22 (left) The same case, from a film made in 1931. There has been complete union between the epiphysis and the diaphysis at the lower end of the radius.

Fig. 23 (right) Case 6. The photograph was made five years after the original observation. The disturbance was limited to a single bone.

or complete. Partial retardation of tubulation leads to exostoses. Total retardation of tubulation leads to long, wide metaphyses.

3 Dyschondroplasia may be limited to a single bone or it may involve almost all of the bones of the skeleton. We have seen involvement of all long bones, and the scapulae, ribs, and pelvic bones as well. It may manifest itself in shortening, bending, or widening of the metaphyses and exostoses.

4 The theory advanced by Jansen explains all of the phenomena which are found.

5 The clinical experience which we have had adds to the weight of evidence in favor of Jansen's theory.

CLINICAL REPORT

The following summaries of cases which we have observed are here presented.

This case is of interest when we compare it with the description of the cases which are to follow. In our other cases we have an almost universal evidence of retardation of tubulation or dissociation phenomena. In this case we have the dissociation phenomena limited to a single bone. In the succeeding cases, dissociation phenomena were both complete and partial, evidenced by the formation of exostoses, as well as long metaphyses. In this case there were no exostoses, but just a retardation of tubulation.

It is comparatively easy at this time to classify this case, but as will be seen from my original notes, rickets, osteitis fibrosa, and endocrine disturbances were considered, only to be finally abandoned. While it may seem rather far-fetched, I believe it, nevertheless, worth while mentioning as a precaution that the absence of a febrile reaction

and other evidences of infection should certainly make one avoid the error of suggesting osteomyelitis as a diagnosis. Giant-cell tumor might possibly have been offered as a diagnosis and the patient operated upon unnecessarily.

The explanation offered by Jansen, I believe, clearly places this case in the category of dissociation phenomena.

Case 6 E A, age 13 years, was first observed on Oct 7, 1926. The diagnosis was dyschondroplasia (Figs 19, 20, 21, 22, 23). There was no history of a definite injury. There was pain in the left wrist, particularly when carrying heavy objects. The child had never stopped her ordinary activities except that her left wrist tired when she was practising on the piano. The condition for which she consulted me had first been noticed about five years before the present examination, at which time she had been taken to another physician.

Physical Examination—The patient is a well developed and well nourished female child, height 4 ft 8 inches. There was nothing unusual to be noted about the contour of the face, the teeth were in excellent condition and no prognathism was noted. The contours of the shoulders were identical. There was no limitation of motion of either shoulder, no noticeable deformity of the scapulae was found.

Examination of the elbow revealed that the carrying angle on the right side was normal. There was a diminished carrying angle on the left, with a deviation to the ulnar side. There was marked bowing of the forearm about two inches above the wrist, which was more noticeable on the dorsum of the forearm when it was pronated. There was a prominence in the antecubital fossa. There was some atrophy of the thenar and hypothenar eminences, and the muscles of the fingers. Palmar flexion was increased, dorsiflexion was limited.

The lower extremities were the same length by actual measurement. The great

trochanters were apparently on the same level. There was no bowing of either thigh or leg, and no limitation of motion of the hip, knee, or ankle on either side.

The blood calcium was 10.5 mg for 100 cc of blood, and the phosphorus content was 0.95 mg for 100 cc of blood. The Wassermann test was negative.

The X-ray films showed a marked bowing of the left radius, the lower portion of the shaft being broader than its fellow. The lower epiphysis of the radius, instead of being transverse, was oblique and irregular. The radiologists (E C Samuel, M D, and E R Bowie, M D) reported "The condition is strongly suggestive of dyschondroplasia."

The appearance was so unusual that Dr. Samuel and Dr. Bowie suggested they would like to have the opinion of another radiologist. Accordingly they sent the films to a distinguished radiologist in a distant city who suggested that the condition was probably a Madelung's deformity.

I advised the mother that I did not believe this to be a Madelung's deformity, but I thought it to be associated with a nutritional disturbance, probably a late rickets or an osteitis fibrosa cystica. Further, I advised her that, if the disease progressed, it would be wise for her to consult either Dr. Joseph Bloodgood, of Baltimore, or Dr. Dallas Phemister, of Chicago.

Following up the idea which we originally expressed, the patient was given a diet rich in calcium and phosphorus, and general body irradiation. She showed no improvement, but there was no progress of the deformity and no other bone of the skeleton became involved. After a short time the treatment was discontinued as I did not believe that we were obtaining any benefit.

From time to time radiograms have been made, the last one in September, 1931. There has been a complete union between the epiphysis and the diaphysis at the lower end of the radius. If we are to take the

The appearance was so unusual that Dr Samuel and Dr Bowie suggested they would like to have the opinion of another radiologist. Accordingly they sent the films to a distinguished radiologist in a distant city who suggested that the condition was probably a Madelung's deformity.

I advised the mother that I did not believe this to be a Madelung's deformity, but I thought it to be associated with a nutritional disturbance, probably a late rickets or an ostertis fibrosa cystica. Further, I advised her that, if the disease progressed, it would be wise for her to consult either Dr Joseph Bloodgood, of Baltimore, or Dr Dallas Phemister, of Chicago.

Following up the idea which we originally expressed, the patient was given a diet rich in calcium and phosphorus, and general body irradiation. She showed no improvement, but there was no progress of the deformity and no other bone of the skeleton became involved. After a short time the treatment was discontinued as I did not believe that we were obtaining any benefit.

From time to time radiograms have been made the last one in September, 1931. There has been a complete union between the epiphysis and the diaphysis at the lower end of the radius. If we are to take the

postulates of Molin as a basis for classification, the bowing and shortening of the radius, the obliquity of the epiphysis, the lack

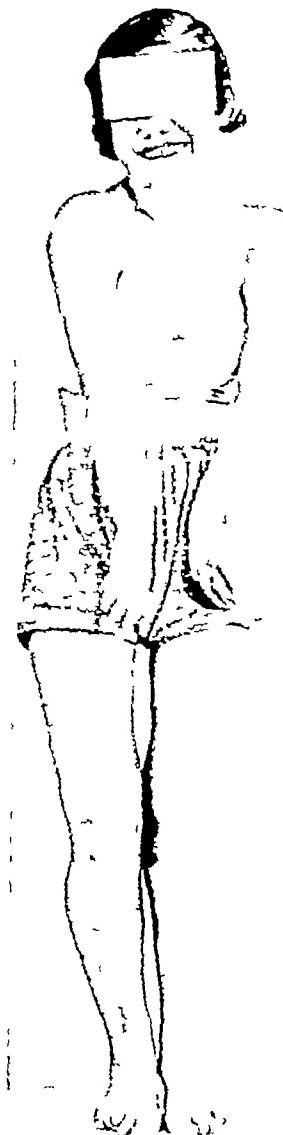

Fig. 24 Case 7 Dyschondroplasia. The nodules are widely distributed over the skeleton. Note the marked bowing of the right forearm and the shortening of the ulna.

of tubulation of the lower end of the metaphysis, and the vacuolization definitely place this case in the group of dyschondroplasia.

Case 7 J C, age 18 years The diagnosis was dyschondroplasia (Figs 24, 25, 26, 27, 28, 29, 30) This report is as of October, 1931

Clinical History—The patient was first seen on May 18, 1921, at which time the following notes were made. From the time the child was three years old, the mother had noticed small nodules near all of the large joints. In every other respect the child seemed perfectly well.

On examination we found widely distributed over the skeleton many large, hard, circumscribed, nodular masses, which were neither adherent to the skin nor tender to the touch. The large nodules were located on the left leg, in the region of the external malleolus, on the right leg, just above the internal malleolus, over the right ulna, in the region of the styloid process, over the left radius and ulna, and a small spur-like mass in the region of the right shoulder.

On account of the great number of masses which were present I advised removal of only those which interfered with function.

Operation—On Oct 7, 1921, the first operation was performed, consisting of linear incision on the inner side of the left knee, the upper limit corresponding to the epiphyseal line of the tibia. Care was taken not to injure the insertion of "hamstrings". Periosteal incision was made and a periosteotome was inserted between the growth and the shaft. The mass was elevated easily and removed *in toto*.

Incision was made along the lower third of the radius midway between the flexor and extensor tendons. The radial nerve came into view very readily and was retracted. The extensor longus pollicis was retracted to the dorsum of the forearm. After retracting the flexor muscles, the periosteum was incised and a periosteotome was inserted between the growth and the radius, and the growth removed. We then found a second growth on the dorsum of the radius which

we removed A small enchondroma on the index finger was removed

On Aug 4, 1922, a second operation was performed An incision about two inches long was made about the external malleolus of the left leg An enchondroma about one and one-half inches in length was easily removed, the only thing necessary was to lift it from the shaft of the fibula by means of a periosteotome

A small incision was made over the dor sum of the right foot, corresponding to the third metatarsal, and a small enchondroma was removed

The girl continued under observation and it was not until 1930 that she noticed an interference with walking because the masses about the lower end of the right tibia had increased markedly in size At that time (August, 1930) a series of X-ray films was made

These films showed that the metaphysis of the upper end of the right humerus ex tended from the level of the anatomic neck to the junction of the middle and upper third of the shaft On the outer side of the region of the great tuberosity there was a large vacuolated mass which was of less density than the normal shaft The upper third of the left humerus showed a marked vacuolization, with a large spur-like mass about two inches below the upper end of the metaphysis The radiogram of the pelvis showed a large mass springing from the posterior iliac crest This mass was much less dense than the remainder of the ilium There was a bilateral coxa vara Each femur had a short neck, and an increased transverse axis of the intertrochanteric line, giving the impression of an interference with tubulation
